W	watt
WL	window level
WW	window width

In human medicine, computed tomography (CT) and magnetic resonance imaging (MR) have become established as important imaging tools with many applications in various clinical disciplines.

Both techniques are also becoming readily available to veterinarians during the last years and subsequently commonly used for the diagnosis of several disorders in small animals.

In this general introduction a brief description is given of

- the physical principles and techniques of CT
- the physical principles and techniques of MR
- the clinical applications of both techniques in the dog

Introduction

Computed tomography (CT) is a cross-sectional imaging technique using x-rays and computers^{1,2}. The tomographic nature of CT images provides accurate anatomic evaluation of tissue planes and regions which are often impossible to visualize with conventional radiography. The ability to image cross-sections makes it possible to build up a three-dimensional picture which is invaluable for understanding normal anatomy and for planning surgical or radiotherapy treatment. High contrast and spatial resolution account for its unsurpassed imaging of bone structure in the clinical setting. Differentiation between fluid and solid tissues and assessment of the internal structure of soft tissues is also possible with CT³ but better results are achieved with MR imaging.

Several types of CT scanners are used. Third- (as used in this study) and fourth-generation units employ a rotating x-ray tube with movable or stationary detectors (Figure 1). Scan time with these units is only a few seconds. Advances in CT technology with reduced scan times (1-2 seconds) and improved reconstruction algorithms combined with thin section CT (1-2 mm section thickness) is known as high-resolution computed tomography (HRCT). With its superior contrast resolution HRCT allows structures as small as 200 μ m to be visualized.

Figure 1: Rotation scanner of the third generation with movable detectors (A) and of the fourth generation with stationary detectors (B).

The fifth-generation scanners were developed primarily for high speed scanning (Figure 2). With the use of spiral CT, the scan time of data acquisition has been dramatically reduced, resulting in a much quicker overall examination, which is especially important in the investigation of small animals in reducing the number of motion artefacts. Thinner slices and faster imaging times are now possible, resulting in increased image resolution^{3,5}.

Figure 2 : Helical scanning : spiral motion of the x-ray tube around the patient as the patient continuously moves through the gantry. As a result of these two motions, all points in the patient are interrogated by the x-rays.

The newest development in CT-scanners is the multislice CT or the multirow-detector CT scanners. These scanners produce multiple (2, 4 and 16) spiral acquisition slices simultaneously and gather a large data set of the scanned volume. This information can be processed in order to provide images of slices in all planes and directions. The newest multislice CT-scanners permit submillimeter collimation slice-width, and can provide an isotropic data set which allows not only an optimal in plane resolution but also an identical spatial resolution of multiplanar-reformatting in all directions: these 'isotropic' image voxels have equal size in all directions⁶.

General principles

THE CT IMAGE

Figure 3 : Composition of the CT image: the smallest square unit of a CT image is the pixel. Each pixel is a two-dimensional representation of a three-dimensional volume of tissue (voxel) from the body slice.

In classic sequential CT, multiple projections of a particular slice of tissue are made and information from all projections is combined to create a single tomographic (slice) image. A complete CT scan consists of a number of slices or images, usually contiguous, through the area of interest. The CT image is composed of a matrix of small tiny squares, called pixels. Each pixel is a two-dimensional representation of a three-dimensional volume of tissue, the voxel. The third dimension of this volume of tissue is the thickness of the slice of the tissue (Figure 3).

The matrix may vary from 256x256 to 1024x1024 pixels. The more pixels in a matrix, the less the transition between the different pixels is visible and) the better the spatial resolution^{2,7}.

The colours that are used are black, white and shades of gray. CT systems can record thousands of grey shades and separate densities ranging from air to high-density metal can be visualised. For every degree of absorption of a particular tissue or object, there is a corresponding shade of grey (see further for window settings). Each tissue has its own characteristic attenuation coefficient¹.

THE CT PROCESS

In CT images, the shade of grey in the pixels represents the linear attenuation coefficient of the tissues in that voxel. The process of CT determines this linear attenuation coefficient to make a useful image⁸. Therefore, all the components of the CT equipment are used: the gantry and the patient table, the computer and display console, and the camera for hard copies (Figure 4).

Figure 4 : A dog lying in ventral recumbency on the patient table in the gantry of the CT scanner.

The gantry contains the x-ray tube, x-ray collimators and x-ray detector. A CT scanner gantry can, within limits, be tilted to angle the scan plane. In CT, the choice of peak kilovoltage (kVp) is usually limited and a high kVp technique is always used. The kVp should be increased for very thick and dense body parts to ensure adequate penetration, and for very dense objects to minimise beam hardening. Because of the limitations of thermal tube capacities with a given focal spot size, the choice of milliamperes seconds (mAs) also depends on the selected kVp. High mAs will increase image detail because it reduces image noise. When thin sections are made, an increase in mAs can compensate for otherwise interfering image noise associated with narrow slice collimation⁹.

Scan time is the time necessary for the x-ray tube to rotate around the patient while making the exposure. A longer scan time may result in improved image detail since the number of projections can be higher, but may cause motion artefacts (including respiratory motion) and can eventually cause x-ray tube heating¹⁰.

Effects of breathing motion are not a significant problem when scanning joints. Obviously, patient motion should be minimised by using general anaesthesia. Because CT scanners use ionising radiation, the anaesthesiologist must take the appropriate radioprotective precautions. Therefore, monitoring of the patient should be done with acoustic monitors or with monitors that have displays that can be seen from a distance¹¹. For protective reasons, the operator site is also behind a protective shield.

The patient lies horizontally on a movable table, in a way that images are transverse to the long axis of the body. First a scout view of the object is obtained by moving the table through the gantry as the x-rays are being emitted while the tube and detectors remain stationary. A scout view is similar to a plain radiograph and is in fact a digital radiograph. The scout view is used to verify patient positioning and to assist the operator in planning the number and location of slices that are required¹².

During CT scanning, an x-ray tube emits the x-ray beam and rotates 360° around the patient. A first collimator, located between the tube and the patient, determines the thickness of the slice (1-10 mm). A second collimator located between the patient and the detector, also influences the slice thickness and limits the interference of scattered x-rays. The thinner the slice, the higher the spatial resolution, but an increased number of slices requires more scan time. Thick slices may result in small lesions remaining undetected because the attenuation information within each tomographic slice is averaged (partial volume effect). Slices of 10 mm are used when scanning the entire thorax or abdomen. In brain CT, 5 mm thick slices are normally used. When it is essential to image the entire object, continuous slices are required. This leads to an increased overall scanning time and tube load. Therefore, thicker slices are often chosen instead. On the other hand, there are body parts and conditions where continuous scanning is not essential. In these circumstances, scanning with a thin slice width and a few mm interval is often a better alternative¹. One must be aware of information gaps between the different sections.

Depending on the kind of tissue and the thickness of the slices, the x-ray beam is absorbed or scattered. The x-ray photons emerging from the patient are absorbed by the x-ray detectors, converted to an electrical signal, amplified and converted into a number (numeric value). This

Image manipulation can be done after the exposure as the image is on the display screen. Regions of interest can be selected and various data computed and displayed regarding them, including size and CT number average and range.

Figure 6 : After the scan examination, the window level and window width can be manipulated. Using a bone window (a) the subchondral details in tibia, fibula and calcaneus are nicely visible. On a soft tissue window (b), the details of tendons and vessels are more clearly visible.

Comparison of CT numbers between different areas on an image is sometimes useful, particularly regarding to relative differences in density¹⁰ (Figure 6).

Image reconstructions

After the scan examination, images in other planes can be produced using computer reformatting. Using data from the transverse slices, images are produced in other planes (Figure 7). It is easier to appreciate the extent of a lesion when it can be studied in multiple planes^{3,14}.

Figure 7 : After the scan examination images can be reconstructed in different planes. A. transversal plane
B. dorsal plane
C. sagittal plane

Three-dimensional (3D) reconstruction is useful in selected cases for obtaining a panoramic view of a lesion and its extent of involvement, particularly in regard to bone lesions. By instructing the computer to eliminate soft-tissue CT numbers, a 3D surface image can be produced and rotated (Figure 8)^{9,10}.

Figure 8 : 3D reconstruction of a canine elbow

Contrast studies

To increase the amount of soft tissue information, negative (air) and positive contrast agents, such as radiopaque iodine can be used. The use of non-ionic contrast agents is advantageous because of their lower incidence of side-effects but they are more expensive than the ionic forms. The ionic, high osmolality contrast agents are less expensive and, in general, adverse reactions are a minimal problem in these cases and especially in veterinary medicine¹⁵. Ionic contrast agents are good for providing positive contrast enhancement of fluid filled cavities e.g. intrathecal injection in CT-myelography, and also for gastro-intestinal and urogenital studies. Intravenous positive contrast is used to differentiate between normal and abnormal tissue¹⁶. Contrast agents can be injected either as a bolus or as an infusion^{15,17}.

Positive contrast techniques are the most important tools in veterinary medicine e.g. for demonstrating brain tumours. Normally, water soluble, iodinated contrast media do not cross the intact blood barrier, but where this barrier is damaged by a lesion, the contrast medium will enter in the interstitium and enhance the radioabsorption of that area. Normal brain enhances only 2-4 HU after the administration of intravenous contrast medium injection (caused by small vascular structures) (Figure 8), but the density of a lesion will increase by 20-40 HU.

Figure 8 : Plain CT image of the skull of a dog (left) and corresponding image after administration of IV contrast medium (right). The vascular structures become visible and the overall density of the brain parenchyma increases.

This enhancement reflects not only vascularity but leakage (transition) of the contrast medium in the intercellular space as well (damaged blood-brain barrier). This phenomenon can be useful for delineating areas of necrosis³.

CT guided biopsies

It is possible to obtain biopsies under CT guidance, a procedure which can be accurately performed when additional information is needed for diagnosis, staging or therapy planning. This approach can be of value for investigating mass lesions resulting from neoplasia or infections. Besides their use in the brain, CT guided biopsies in dog and cat appear to be particularly useful for lesions involving the retrobulbar space, the paranasal cavities, the vertebrae and ribs, the pelvis, and the lung and mediastinum¹⁸⁻²⁹. Although stereotactic devices and guidance devices improve the accuracy, free-hand techniques are commonly used. CT guided percutaneous biopsy can be performed using a fine aspiration needle, a tru-cut needle to obtain tissue core samples, or a bone biopsy needle. When performing CT guided needle biopsies, precise needle tip localisation is an essential skill²⁷.

The retrobulbar region is directly accessible to biopsy due to the incomplete bony orbit of the dog. Care must be taken not to damage the optic nerve and the external ophthalmic artery³⁰. A percutaneous CT guided needle biopsy of deep lesions such as a vertebral body or intervertebral disc can be performed in a safe and accurate way^{28,31}.

CT guided aspiration in the thoracic cavity of lymph nodes or pulmonary masses may result in a cytological diagnosis. Intravenous injection of contrast medium delineates vessels immediately adjacent to a mass. During the puncture procedure, vessels can be avoided and the safety of CT guided biopsies in the thorax can be improved²⁹.

Stereotactic devices are normally used for obtaining brain biopsies. They are rather expensive and complicated, as they have to be adaptable to the different possible skull sizes in dogs. Because most of the time the CT findings do not allow an exact histological diagnosis, biopsies are extremely useful in treatment planning^{32,33}.

Radiation therapy

Radiation therapy is used to treat inoperable tumors that have not spread to other sites in the body. It works by sterilizing cells, which keeps them from being able to undergo successful division. The classic method for developing the beam geometry for radiation therapy planning is to use a conventional 'simulator', i.e. a radiographic/fluoroscopic system that is geometrically equivalent to the linear accelerator used for treatment³⁴. The linear accelerator can be programmed to produce photons or electrons in order to treat deep or superficial tumors, respectively. The planning data include therapeutic beam angles, shapes and isocenters. The fluoroscopic imaging of a conventional simulator provides the physician with views of the patient's internal anatomy, but due to limitations in soft-tissue visualization the tumor itself is often not shown³⁴.

With the advent of CT simulation the use of conventional simulators has diminished significantly. CT simulation can create synthetic X-ray projections from CT image volumes, referred to as Digitally Reconstructed Radiographs. These enable the radiation oncologist to simulate treatment with the added benefit of better soft-tissue visualization. The CT volumetric data also facilitates planning the 3D distribution of the radiation dose³⁴.

The main objective of external beam radiation therapy, including the more advanced 3D conformal radiation therapy, is to apply a local radiation dose, prescribed by a radiation oncologist, to a solid tumor within the planned treatment volume. In addition, the dose to nearby organs and critical structures must be minimized in order to avoid treatment related complications³⁴.

Respiratory motion, i.e. excursion, is one factor that adversely affects the objectives outlined above. Recently, new visualization methods have been developed for radiation therapy planning with respiratory gated, multiphasic CT data sets. The system enables the visualization of respiratory

movements, helps to identify patients with minimal tumor movement, and reduces the tumor margins needed to keep the tumor in the treatment beam³⁴.

2. TECHNICAL ASPECTS OF MAGNETIC RESONANCE IMAGING:

Review of literature

Introduction

In 1980, Holland et al. reported on their first experiences with magnetic resonance imaging (MR)¹ and the technique became available for clinical use in 1983². The MR imaging principle fundamentally differs from CT, using radio waves and magnetism to measure nuclear magnetic resonance emitted from protons instead of x-rays attenuated in tissue¹. MR had several advantages over CT, due to its inherently high sensitivity to soft tissue contrast, its ability to manipulate the signal intensity of various soft tissues by the use of a different pulse sequence, and its ability to generate images in different planes directly, rather than by reformatting, in transverse, dorsal, and any other plane desired³.

Initially, MR was used almost exclusively for evaluation of central nervous system (CNS) lesions². Its chief advantage over CT in this region was the ability to image the caudal fossa of the brain without the artifacts frequently seen with CT scans of this area, the improved detail of the images, the ability to acquire images oriented in any plane, and to differentiate extravascular blood from surrounding structures³. However, shortly afterwards, it became clear that MR was also very well suited for evaluation of the musculoskeletal system². For evaluation of the disorders of various structures of the musculoskeletal system, including bone marrow, muscles, tendon ligaments, fat tissue, articular cartilage, menisci, intervertebral disks in the cervical and thoracic region, and for spinal cord and nerve roots, it is a useful diagnostic imaging modality². MR also shows superior anatomic detail of soft-tissue structures in case of abdominal disorders. Motion artifacts on images involving the chest cavity are considerable, but new breath-hold sequences and cardiac gating techniques have improved the ability to image this region.

It is now evident that MR probably represents the most significant advance in diagnostic medicine since the discovery of x-rays, and each year brings new hardware and software advances⁴. The technique has almost totally supplanted some of the classic diagnostic modalities such as arthroscopy, and is now seriously challenging angiography².

General principles

IMAGE ACQUISITION

Components of the system include the magnet, coil, and computer station. The magnet surrounds the gantry and allows the establishment of a magnetic field. A copper coil is positioned in the gantry, parallel to the external magnetic field, and surrounds the region to be imaged. The function of the coil is to detect radiofrequency signals produced by changes in the animal's magnetic field⁵.

The computer station allows the programmer to set parameters for the image study, formulates and transmits instruction for the production of a radiofrequency pulse sequence directed at the region of interest, and analyzes the sampled data to produce the image^{5,6}.

Figure 1. MR scanner with the patient table and the gantry containing a magnet and a copper coil.

MR represents the unstable portion of an animal's own magnetic field, and images are produced through the interaction of radiofrequency waves and hydrogen ions of tissue within a magnetic field. Nuclei of elemental substances are composed of protons and neutrons.

Figure 2 : Nucleus of an atom surrounded by protons and neutrons

The moving or spinning of electrically charged particles (protons) creates the magnetic field of the nuclei. These structures are in constant motion, spinning about the internal axis of the atom, giving the particles angular momentum(= magnetic capacities).

Protons have positive electric charge and "spin" which results in their behaving like little dipole magnets.

Because remember a moving electric charge (i.e. electric current) produces magnetic field

However, not all atoms possess spin. When evenly paired (same number of each particle type), the spin of a particle is opposite that of its paired particle, and the nucleus has a net angular momentum of zero. When the total number of particles is odd (1,3,5, etc) the unpaired particle's spin yields the angular momentum force for the nuclei. Tissue components with spin can be measured with MR; those without spin cannot. Hydrogen (^1H), for example, has an atomic number of 1 and only a single proton, possesses spin, and is a common component of biologic tissue. Sodium (^{23}Na) and phosphorus (^{31}P) also possess spin; whereas carbon (^{12}C), oxygen (^{16}O), and calcium (^{40}Ca) do not have spin. In summary, with conventional MR, tissue with high hydrogen content (e.g., water, fat) are imaged; regions of bone or air appear void³.

Within the bore of the magnet, the external magnetic field is considerably stronger than the biologic field, causing the biologic field to align with the external field. Within the bore of the magnet, the biologic field and the external magnetic field are in a state of equilibrium.

When in an external magnetic field, their lowest (preferred) energy state is to line up with the field.

But only slightly more than 1/2 of the protons will actually line up, the others will be in the opposite orientation. The stronger the field, the more will line up.

To measure the animal's magnetic field and avoid interference from the external field, it is necessary to disturb the biologic field. This alteration of the biologic field is accomplished using a specified sequence of magnetic pulses and taking advantage of the resonance phenomenon.*

This additional magnetic field (magnetic pulse sequence) is applied as a cyclic force at the natural frequency of the animal's nuclear field (spin) and perpendicular to the external magnetic field. The effect is a "tipping" or nutating of the animal's nuclear magnetic field. The degree of nutating is governed by the strength and duration of the magnetic pulse⁵.

Application of a magnetic pulse sequence imparts minute amounts of energy to atomic nuclei. If the particle possess spin, it precesses around the external field, in a manner similar to that of a gyroscope. Particles without spin simply fall back to the external field with each cessation of the magnetic pulse. The rate of precession for a particle is called the Larmor frequency and is determined by the gyroscopic properties of the atomic field and the strength of the external field. In MR, magnetic pulse sequences are applied perpendicular to the external magnetic field and at the Larmor frequency for (¹H) hydrogen (42.58 MHz/T; T = tesla, a measurement of external magnetic field strength). As a result the patient's (biologic) magnetic field undergoes two simultaneous Larmor precessions: one around the external magnetic field and one around the rotating (cyclic)

**A system's response to an external cyclic force applied at the system's natural frequency of cyclic motion will be larger than for any other frequency of an external cyclic force⁵.*

magnetic field applied in the pulse sequence. This allows the steady tipping or nutation of the biologic field. If a different frequency is applied, nutation does not occur⁵.

After nutating the biologic field to the desired degree or angle, the magnetic pulse is discontinued, and the biologic field realigns with the external field. Application of specific strengths and durations of the magnetic pulse results in the production of measurable radiofrequency waves created by realignment of the nuclear field (=relaxation). Only the tissue components with the same natural cyclic motion (spin) frequency as the applied magnetic pulse (cyclic force) create these measurable radiofrequency waves.

A coil, placed parallel to the external magnetic field, detects the radiofrequency waves, which are transmitted to a computer station. The computer analyses the data received, using for example a Fourier transformation, to construct the resultant image⁵.

The production of a MR image from biologic tissue involves the process just described. The natural frequency at which the cyclic force is applied is that of the ^1H (hydrogen) ion. The most often used magnetic pulse sequence for imaging is the spin echo pulse sequence^{5,6}. The magnetic pulse is initially applied to mutate the nuclear field 90° and, after specified time, a second pulse produces a 180° rotation in the transverse plane.

A delay occurs before the next 90° pulse, and during the delay the radiofrequency waves (=echos) are sampled by the coil. The time between the 90° pulse and the detection of the radiofrequency waves by the coil is termed the echo time or TE. The time lapse between each 90° pulse is termed

the repetition time or TR^{5-7} .

Image contrast is mainly controlled by the TR and TE. The proper TR and TE combinations are selected to produce image contrast related to differences in proton (1H) density, T1-relaxation time (see further), and T2-relaxation time (see further). A marked change occurs in the magnitude of the magnetic field during the relaxation phase of the realignment process (following cessation of a magnetic pulse). During relaxation, the magnetic field contains two components termed longitudinal and transverse magnetization.

Relaxation times are related to the rate at which a given tissue can absorb or release radiofrequency waves. T1-relaxation concerns the spin-lattice interaction, this refers to the change of energy by protons (spinners) with surrounding nonproton structures. The movement of the longitudinal field back to an equilibrium point occurs at a rate specific for each tissue and is called the T1-value for that tissue. The time needed to restore 63% of the original longitudinal magnitude is called the T1-relaxation time. Contrast related to T1-differences in tissue is controlled by the TR. Images that are T1-weighted are equated with short TR times to make the differences between tissues with different T1-relaxation times more clearly. Tissues with short T1-relaxation time e.g. fat (fast change of energy to the surrounding tissue and fast relaxation) are brighter (more intense), and tissues with longer T1-relaxation time e.g. CSF (cerebrospinal fluid) are darker (less intense). There is a difference between free (urine, CSF, cysts) and bound (brain, pancreas, liver) water: Free water moves quickly, so the energy-transfer is difficult. Longitudinal relaxation is slow. T1-values

are slightly longer. Bound water (intra- and extracellular) will transfer the energy in an easier way to the surroundings, there is more recovery with a certain TR, the T1-values are slightly shorter. Most benign tumors have large intracellular spaces containing bound water, so its T1-values are shorter as is urine/csf. Most malignant tumors have large, bad organized cells, containing more free intracellular water and extracellular water; its T1 is longer!

TE is also kept short so T2-values will not be able to influence the signal.

$T_1 = f(\text{Longitudinal relaxation time})$

The process of lining up with the field is called longitudinal relaxation.

The time it takes for this portion of the protons get lined up with the magnetic field is a function of " T_1 " - the smaller (shorter) T_1 is, the shorter the time to line up (become "magnetized").

T_1 is different in different types of tissues (water = long T_1 , fat = short T_1).

There is another possibility to make an image. Take a long TR (all tissues relaxed) a short TE (no T2) so the picture will depend on the amount of protons in this tissue. Much protons give high signal, less protons low signal. This proton density (PD) is tissue specific. (The PD of muscle is 100, as is white matter; fat 98, liquor 96, blood 90, bone 1-10, air <1). The difference between T1 and PD imaging: T1 is depending on the speed of relaxation in the longitudinal direction, PD is depending on the maximum relaxation of the tissue. That's why for T1, the TR is short and for PD the TR is long. (TR 3 times the T1 value of the tissue will produce PD contrast). The TE must be short (T2 influences).

T1 and TR

T1 = recovery of longitudinal (B_0) magnetization

- T1 contrast used in anatomical images
- ~500-1000 msec (longer with bigger magnetic field)

TR (repetition time) = time between excitation pulses

Source: Mark Cohen's web slides

Concurrently, the transverse field decays toward zero during relaxation at a rate proportional to the magnitude of the tissue, the time needed to let the protons(tissue) dephase for 37% is called T2-relaxation time. T2-relaxation concerns the spin-spin interaction, which refers to the exchange of energy by protons with other protons⁵. The more protons that have a magnetic resonance component in the transverse plane, the higher the signal.

T2 and T2*

$= f(\text{time to get out of phase})$

If they are all at the same point in their precession cycle, (i.e. "in phase") then their signals will add together.

The contrast related to the T2 differences in tissue are controlled by the TE. With a short TE the difference in signal intensity is less pronounced than after a longer TE.

The T2-weighted image is produced by a longer TE but also by a longer TR⁵. TR is long so all tissue protons can go back to the transverse plane with the next RF pulse. Tissue with longer T2-times is brighter (more intense), and tissue with shorter T2 times is darker (less intense). For example : the spin-spin energy transfer of water is more difficult because of fluctuating molecules (=long T2-relaxation time, bright). Fat will dephase faster than water (short T2, dark), so the water signal is more T2-weighted.

With short TE and long TR, the picture is depending on the amount of protons in the tissue (PD weighted).

TR: 250-700 ms = SHORT TR: >2000 ms = LONG

TE: 10- 25 ms = SHORT TE: > 60 ms = LONG

For spin echo images, the following apply: T1 and T2 effects occur simultaneously, but T1 effects dominate T1-weighted images and T2 effects dominate T2-weighted images⁵.

The MR examination :

IMAGE ORIENTATION

The MR examination usually consists of acquisition of T1-weighted and T2-weighted images of an anatomic region (e.g., brain) in one or more planes. Images may be oriented in sagittal, transverse (axial), or dorsal (coronal) planes. MR acquisition can be oriented in any plane, regardless of patient orientation inside the magnet. This property of MR does not require computer generated

reformatting of data obtained in one plane and can therefore be performed without sacrifice of image quality⁷.

DATA ACQUISITION

A multislice acquisition technique is used, allowing simultaneous acquisition of image data from several tissue slices within the chosen field of view. Slice thickness is chosen based on the purpose of the examination and the area being imaged. For a MR brain scan in a dog, one author has used a 4 mm slice thickness⁹. Thinner slices offer better resolution, but image quality suffers because the signal produced is related to the volume of tissue being pulsed (signal-to-noise ratio). Volume coverage also is reduced^{5,6}.

Field of view and matrix size are additional parameters to be addressed. Smaller fields of view may increase the spatial resolution, but at the expense of signal-to-noise ratio. An increase in matrix size will also increase spatial resolution, but with loss of signal-to-noise ratio. Most scans are performed using a 256 x 256 matrix size⁶.

The TR and TE times vary with the desired image characteristics, the tissue being imaged, and the strength of the magnet. Most magnets in use at human imaging centers are 1 to 1.5 T in strength. T1-weighted images are obtained at a TR of 300 to 600 msec and a short TE of 20 to 30 msec and for the T2-weighted image, TR = 2000 to 3000 msec and TE = 60 to 80 msec is used^{5,6,10}.

Other parameters are important in the operation of the MR scanner, such as imaging gradients, but are beyond the scope of this review and are best addressed in the references listed.

PATIENT PREPARATION

The animal is, dependant on the area of interest, positioned in ventral or dorsal recumbency, with the head entering the gantry first. Consistent positioning for all imaging procedures facilitates image interpretation and identification of right and left sides. Near perfect symmetry aids in the ability to correctly interpret the images. If one side of the head is rotated more rostrally than the other, for example, many structures (e.g., lateral ventricles) will appear asymmetrical on the scans, and this could lead to an erroneous diagnosis⁷. An asymmetric position of the patient can also be corrected on the MR-images by adjusting the image plane on the scanogram.

A scout film is initially made to determine patient position in the gantry and to identify the region to be imaged. Slice thickness and the number of scans necessary for the study are determined before continuing the procedure. This ensures that the area of interest is contained in the completed study⁷.

IMAGE CHARACTERISTICS AND PRINCIPLES OF INTERPRETATION

Unlike conventional radiologic and CT techniques, which are almost completely dependent on differences in electron density of tissue, MR reflects complex interactions of the T1- and T2-times and proton (^1H) density. T1 and T2 are intrinsic tissue characteristics and are representative of the relative content of water molecules^{5,6}. Subtle changes in the blood-brain barrier can be reflected in T2-weighted images as abnormal accumulations of water, well before being evident on T1-weighted images, T1-weighted contrast images, or CT¹⁰. Tissue contrast is considered the most clinically relevant attribute of MR⁵. T2-weighted images are considered the most sensitive in this regard, whereas T1-weighted images show more specificity in anatomic structure.

Like CT images, MR images are representations of each voxel, constructed from an array of numbers representing computer data, and displayed as two-dimensional structures termed pixels^{5,6}. A fundamental difference exists, however, in the pixels of CT and the pixels in MR. CT scanners are calibrated so that pure water has a zero value (CT number or HU) and air has a value of -1000. Other structures have values based on these calibration units as determined by their relative electron density. With MR, pixel values have no absolute values, and the same structure imaged on different scanners or on the same scanner on two separate occasions may have very different signal intensities, even if the TR, TE and other parameters remain the same. However, relative differences in tissue density (for instance, CSF versus white matter) will remain constant, but other factors such as patient positioning within the coil and how the scanner is tuned are often responsible for the differences in the signal intensity⁶.

Rapid flow, e.g. of blood or CSF, creates a signal void. This is because the hydrogen containing components of the fluid, present at the time of the radiofrequency pulse in the slice being imaged, do not remain within the voxel long enough to encounter both the 90° and 180° pulses and therefore do not produce a signal. Slower-moving fluid can produce the opposite effect and appear bright. This occurs because the slower-moving fluid is less saturated with signal produced from multiple radiofrequency pulses, and all tissue loses some signal from this process. The slower-moving fluid encounters fewer total radiofrequency pulses, loses far less signal from saturation, and produces a higher signal intensity⁶.

Increased water content of tissue (CSF, edema) results in an increased signal intensity on T2-weighted scans and a decreased signal intensity on T1-weighted scans (Figure 3). Increased signal intensity on T1-weighted scans is noted with the presence of fat, melanine, manganese, some calcifications and methemoglobin (e.g. cerebral hemorrhage during day 7-21). Decreased signal

intensity noted on gradient echo T2-weighted images may suggest flow or intracellular degradation products of hemoglobin (cerebral hemorrhage during all stages)⁶.

Figure 3 : T1-weighted (left) and T2-weighted (right) transverse images of the canine brain at the pituitary level. Note the increased signal intensity of the CSF on the T2-weighted image. (With permission of R. Dennis, New Market, UK.)

Interpretation of MR scans begins, as with any radiologic technique, with a thorough knowledge of the anatomy of the imaged structure. Additional considerations are the ability of MR to image any plane and the need to recognize structures imaged using sagittal, transverse, or dorsal planes.

Contrast studies

In addition to T1- and T2-weighted images, and depending on the purpose of the examination, the T1 study may be repeated with the intravenous injection of gadolinium-DTPA (Gd-DTPA) for contrast enhancement^{6,8} (Figure 4). Gd-DTPA is a paramagnetic substance, having an unpaired electron which magnetic moment is 700 times stronger than the one of the proton, and due to dipole-dipole interactions it causes adjacent hydrogen nuclei to relax more quickly^{6,8}. On T1 studies, the image of tissues containing the contrast agent appears more hyperintense. This provides more sensitive detection of various lesions, especially in the central nervous system, better defines margins of the lesions and allows more accurate differentiation of lesions^{6,8}. The resultant effect is much the same as for iodinated contrast agents used in computed tomography imaging studies⁶.

Figure 4 : Pre- (left) and postcontrast (right) T1-weighted images of the canine brain. Tissues containing the contrast agent appear hyperintense. (With permission of R. Dennis, New Market, UK.)

**3. CLINICAL APPLICATIONS OF COMPUTED TOMOGRAPHY
AND MAGNETIC RESONANCE IMAGING
IN SMALL ANIMALS :
Review of literature**

Detection of lesions in animals on CT and MR images is possible by virtue of displacement or deformity of normal landmarks (mass effect) or by changes in tissue composition due to pathological processes such as oedema, haemorrhage, necrosis, calcification and osteolysis¹.

In small animals, CT and MR are particularly valuable for the detection and diagnosis of brain disorders²⁻⁷¹. The fact that some intracranial lesions may not be visible on CT is due to diffuse distribution, attenuation levels similar to those of the surrounding normal tissue, and minimal or absent contrast enhancement. CT and MR are also very helpful in the investigation of spinal cord lesions in the event of doubtful radiographic and/or myelographic findings⁷²⁻⁹¹ and in the detection of disorders of the peripheral nerves⁹²⁻⁹⁶. Musculoskeletal CT and MR⁹⁷⁻¹¹⁶ may be helpful in clinical cases in which standard radiography and ultrasonography are negative or inconclusive, even though there is a high suspicion of pathology. For example in the diagnosis of fragmented coronoid process, CT has been proven to be superior to radiology¹¹⁷. For the detection and description of masses, malformations and fluid collections in the thoracic cavity¹¹⁸⁻¹²⁸, CT is the best imaging modality and is considered the most sensitive method for the detection of pulmonary metastases¹²⁴. CT and MR of the abdomen¹²⁹⁻¹³⁷ give excellent anatomic images of the organs and vessels, but as a consequence of the overall availability of ultrasound the demand for abdominal CT and MR studies is low.

In evaluating the localisation and the extent and in characterising of lesions of the nasal cavities, paranasal sinuses, orbita, jaws, temporomandibular joints and tympanic bullae, CT and MR are more accurate than conventional radiography¹³⁸⁻¹⁶¹. CT appears to be remarkably accurate in revealing the location, extent and origin of nasal diseases and neoplasia^{140,152,155,159}, and is also superior to conventional radiography for detecting middle ear diseases¹⁴⁶.

Besides for the diagnosis and delineation of the extent of the lesions, CT and MR are also useful in small animals for tumor-staging, planning surgery^{95,162} and radiation therapy¹⁵¹, and as a guide for biopsies of bone or soft tissues¹⁶³⁻¹⁷⁴. External landmarks and depth measurements are used to localise the lesions.

SCIENTIFIC AIMS

CT and MR are novel techniques to perceive anatomical structures on images. On CT and MR pictures, the radiologist is confronted with detailed anatomical cross-sections instead of two-dimensional “shadow pictures” as on conventional radiographs. These new developments have caused difficulties when interpreting CT and MR images, because the knowledge of the normal three-dimensional anatomy and conventional radiographic anatomy could no longer serve as a basis for recognizing structural abnormalities in diseased animals.

To provide an accurate interpretation of CT and MR images and to recognize abnormalities that may be found, knowledge of the cross-sectional anatomy of normal animals is a prerequisite. Therefore a detailed anatomical description of several regions of the body, as revealed by the use of CT and MR, is necessary for the clinician. The aim of this study was to provide a comprehensive atlas of the normal canine body comparing cross-sectional anatomical slices to CT and MR images. Besides the descriptive anatomical aspect of this work, a comparative aspect is added as the results of CT anatomy are compared to those revealed by other imaging techniques such as MR and endoscopy. By combining CT pictures showing the calcified structures with MR scans of the same region, and taking advantage of the MR characteristics of depicting soft tissue in great detail and in superior spatial resolution, a unique atlas has been created.

Several publications on CT and MR anatomy of the dog are already available¹⁻¹⁶ and an atlas of MR and CT of the dog has recently been published¹⁷. Despite the partial overlap with these previous publications, the present work differs as a large number of matching cross-sectional anatomical colour images is used to clarify the corresponding CT/MR images, which provides more detailed and additional information. Every possible effort was made to label in great detail all anatomical structures depicted on the images.

As a complete cross-sectional description of the entire normal canine body should be too overwhelming, a number of representative and clinically important regions has been selected for this study.

The first part of this study describes and compares the CT and MR anatomy of two regions of the head, i.e., the canine brain (chapter 1.1) and the nasal cavities and frontal sinuses (chapter 1.2).

In the second part of this study the anatomy of the thorax is described as revealed by CT (chapter 2.1.1) and by thoracoscopy (chapter 2.1.2), followed by a comparison between both techniques (chapter 2.1.3).

In the third part of this study, the CT and MR anatomy of the elbow (chapter 3.1) and the tarsus (chapter 3.2) are described, and both techniques are compared for each joint.

of the
HEAD**

1.1. The brain

The next two chapters concern the investigation of the brain of the clinically normal dog. In the first chapter (chapter 1.1.1) the computed tomographic examination of the brain is described. The second chapter (chapter 1.1.2) briefly handles the magnetic resonance of the brain and gives a comparison between the results of the 2 techniques, CT and MR. .

However, all figures (anatomic, CT and MR sections) of the canine brain are combined in figure 2 of the first chapter (chapter 1.1.1) to make a visual comparison easier and simple.

1.1.1. Computed Tomography and Cross Sectional Anatomy of the Normal Canine Brain

SUMMARY

Objective—To provide a detailed anatomic description of brain structures in clinically normal dogs by means of computed tomography (CT).

Animals—4 clinically normal adult German Shepherd Dogs weighing 30 to 35 kg.

Procedure—Each dog was anesthetized and positioned in dorsal recumbency for CT examination of the brain; transverse scans were completed at 2-mm intervals from the cribriform plate of the ethmoid bone to the cranial part of the atlas by use of a third-generation CT scanner. Contrast material was injected IV, and a second series of scans was completed. Images (with or without contrast) from all dogs were reviewed by use of a soft tissue setting (window width, 150 Hounsfield units; window level, 50 Hounsfield units). One of the dogs was euthanatized, and a 3.5% formaldehyde solution was perfused via the common carotid arteries. After fixation, the brain was embedded in gelatin and sectioned into 5-mm-thick transverse sections by use of a stainless-steel knife. Anatomic sections were photographed and compared with the corresponding CT views.

Results—Most features of the brain that were identified on anatomic sections could be identified on the corresponding CT scans despite the low contrast between structures, particularly if adjacent bony structures and cerebrospinal fluid (CSF) were used as landmarks. Additional anatomic structures surrounding the brain were also identifiable on the CT images.

Conclusions and Clinical Relevance—Images obtained in this study could be used as a guide for evaluation of CT images of the brain in dogs with brain diseases.

INTRODUCTION

In human medicine, computed tomography (CT) is an important tool for investigation of intracranial disease. During recent years, the technique has become more available to veterinarians and CT of the brain has supplemented conventional radiography for the diagnosis of intracranial disorders in animals. In horses, dogs, cats, sheep, and goats, several pathologic conditions of the brain, such as congenital abnormalities, acquired hydrocephalus, neoplasia, inflammatory and neurodegenerative disorders, infarction, hemorrhage, and cysts, have been investigated and diagnosed by means of CT.¹⁻³² In addition to the diagnosis of intracranial disorders, CT can also be used as a presurgical tool³³ and to provide guidance for brain biopsy procedures.³⁴⁻⁴⁰

To accurately interpret CT scans of a brain, a thorough knowledge of the anatomic features of clinically normal brains is a prerequisite. In the veterinary medical literature, some anatomic features of clinically normal brains of dogs (determined via CT) have been described.⁴¹⁻⁴⁹ The purpose of the study reported here was to provide a detailed anatomic description of brain structures in clinically normal dogs by means of CT. Unlike the previous studies, this study was intended to provide cross-sectional images of the anatomic features of the brain (in color) with more detailed labeling of the gross sections and corresponding CT images as a reference guide for other investigations. Subsequently a comparison between the results of this chapter and the results of the MR examination of the brain (chapter 1.1.2) is made.

MATERIAL AND METHODS

Animals—Four clinically normal adult German Shepherd Dogs weighing 30 to 35 kg were used for this study. None of the animals had a history of neurologic disorders, and physical examination of the dogs revealed no pathologic conditions. The animals were maintained and procedures were performed in accordance with the Ethical Committee of the Faculty of Veterinary Medicine, Ghent University.

Computed tomography—Each dog was sedated by use of fentanyl (0.005 to 0.01 mg/kg, IV) and droperidol^a (0.25 to 0.5 mg/kg, IV); anesthesia was induced via IV administration of thiopental

sodium^b (8 mg/kg). Dogs were intubated and anesthesia was maintained with halothane^c (1.5% to 2%).

For CT examination, each dog was positioned in dorsal recumbency with the forelimbs extended caudally. A lateral survey view was obtained by use of a third-generation CT scanner.^d Settings for the CT image technique were 120 kV and 130 mA. Transverse CT scans of the brain were obtained at 2-mm intervals from the cribriform plate of the ethmoid bone to the cranial part of the atlas, perpendicular to the long axis (or hard palate) of the skull. Following this series of scans, iohexol^e (1 mL/kg) was injected via a catheter in a cephalic vein, and a second series of scans identical to the first series was completed 5 minutes after injection of contrast material. Individual images (obtained before and after contrast administration) from all 4 dogs were reviewed by use of a soft-tissue setting (window width, 150 Hounsfield units; window level, 50 Hounsfield units), formatted on x-ray film,^f and evaluated by 2 investigators (LMDR and IMG).

Comparison of CT and anatomic images—At the end of CT examination, 1 dog weighing 31 kg was euthanatized while anesthetized for reasons unrelated to neurologic conditions. For euthanasia, a combination^g of embutramide, mebenzoniumiodide, and tetracaine (0.3 ml/kg) was injected intravenously during anesthesia. Following euthanasia, a 3.5% solution of formaldehyde was injected via the common carotid arteries until total perfusion of the brain was achieved. Subsequently, the head was separated at the atlantooccipital joint, and the skin, temporal muscles, calvaria, and dura mater were removed. The skull with the exposed brain was placed in a 3.5% solution of formaldehyde for 3 days; the brain was removed and maintained in the same solution for another week. At the end of this period, the brain was embedded in gelatin and sectioned into 5-mm-thick transverse sections by use of a stainless-steel knife. The rostral surface of each anatomic section was photographed; for each photograph, a corresponding CT image was selected on the basis of appearance. Matched pairs of images of the brain were obtained at 17 levels (from rostral to caudal brain regions). One person (LMDR) identified the anatomic structures on the photographs of the sections with the aid of texts on canine anatomy.^{50,51} The identified structures were subsequently located on the corresponding CT images (without contrast material), and afterwards, the list of labeled structures was evaluated on CT images of the 3 other dogs. Nomenclature used for designating all structures was in accordance with official anatomic terminology.⁵²

RESULTS

Seventeen transverse planes of the canine brain, extending from the cribriform plate of the ethmoid bone to the cranial part of the atlas and perpendicular to the hard palate, were matched with their corresponding anatomic section (Figure 1). Structures identified on the anatomic sections were also identified on the corresponding CT images without contrast material (soft tissue window setting; Figure 2).

Figure 1 – Lateral computed tomography (CT) survey view of the brain of a clinically normal dog indicating the levels (A through Q) at which the CT images were obtained. The CT scans were performed perpendicular to the hard palate.

On anatomic sections, numerous structures of the canine brain were identified, including the lobes of the cerebral hemispheres and the longitudinal cerebral fissure. On the rostral anatomic sections (levels A through G), various parts of the telencephalon such as the fornix, corpus callosum, rostral commissure, septum pellucidum, internal capsule, and the caudate nucleus were very distinct. The olfactory bulbs, peduncles, and tracts could be identified ventral to the cerebral hemispheres. At the level of the diencephalon, the optic chiasm was distinguished.

On the more caudal anatomic sections (levels H through L), identifiable structures of the telencephalon included the piriform lobe, hippocampus, and the hippocampal gyrus and sulcus. Several diencephalic structures such as the thalamus, hypothalamus, mamillary body, infundibulum with infundibular recess, hypophysis, epiphysis, lateral and medial geniculate bodies, and the interthalamic adhesion were observed. From the mesencephalon, the cerebral peduncles with the interpeduncular fossa, the rostral and caudal colliculi, the red nucleus, and the substantia nigra were distinct.

113 = Third ventricle.
114 = Tracheotube.
115 = Transverse cerebral fissure.
116 = Tympanic cavity.
117 = Zygomatic arch.

On the most caudal sections (levels M through Q), parts of the metencephalon such as the cerebellar hemispheres, the vermis, and the floccular lobe were clearly visible. Dorsal to the cerebellum, the transverse cerebral fissure formed a major landmark. Prominent ventral structures included the pons, the middle cerebellar peduncle (brachium pontis), and the medulla oblongata with the pyramids flanking the median ventral fissure.

In addition, the various parts of the ventricular system were distinguished. These included the lateral, third, and fourth ventricles; mesencephalic aqueduct; central canal; and choroid plexuses.

On the CT images without contrast material (soft tissue window setting), most of the aforementioned structures could be located by the use of landmarks such as adjacent hypodense CSF and hyperdense bony structures. The position of the longitudinal cerebral fissure was determined by the presence of the hyperdense falx cerebri.

On the rostral CT images (levels A through G), the corpus callosum and caudate nucleus were located adjacent to the hypodense lateral ventricles. The corpus callosum appeared as a moderate hyperdense and V-shaped structure. The fornix, septum pellucidum, and the rostral commissure were identified with reference to the adjacent hypodense third ventricle. It was not possible to distinguish the internal capsule. Several parts of the olfactory system were not distinct but could be identified by their ventral and lateral position in the brain. The hyperdense optic chiasm was identified dorsal to the basisphenoid bone and ventral to the third ventricle.

On the more caudal CT images (levels H through L), the hippocampus was located ventrolateral in the brain and dorsal to the third ventricle and the piriform lobe. The hippocampal gyrus could not be clearly seen. The hypophysis was identified dorsal to the bony hypophyseal fossa. The internal carotid artery was moderately hyperdense and located lateral to the hypophysis; dorsal to the hypophysis, the mamillary bodies and the hypodense hippocampal sulcus were identified. The position of the thalamus could be clearly defined by its margins; however, the optic tract, epiphysis, infundibulum, and tuber cinereum were impossible to distinguish. With regard to the mesencephalon, only the cerebral peduncles could be located lateral to the bony dorsum sellae turcicae. The geniculate bodies were difficult to see but were located dorsal to the cerebral peduncles.

On the most caudal CT images (levels M through Q), the transverse cerebral fissure was identified because of the presence of the hyperdense osseous tentorium cerebelli. Ventral to the tentorium cerebelli, the vermis and the adjacent cerebellar hemispheres were identified. The cerebellar white matter, floccular lobe, and the middle cerebellar peduncle (brachium pontis) could not be distinguished. The pons was determined to be dorsal to the occipital bone, but it was not possible to identify the medial ventral fissure and the pyramids of the medulla oblongata. From the ventricular system, all 4 ventricles and the mesencephalic aqueduct could be located by the presence of radiolucent CSF. In contrast, the central canal and the choroid plexuses of the lateral and fourth ventricles were not detected. The fourth ventricle was not always very distinct because of streak artifacts at the level of the caudal cerebral fossa.

In addition, surrounding bony and soft tissue structures observable on the CT images were also identified and labeled with reference to the anatomic sections and anatomy texts. In the ventral parts of the images, the nasopharyngeal cavity, soft palate, and the root of the tongue were identified. Several cranial muscles (eg, the pterygoid, masseter, retractor bulbi and temporal muscles) were distinguished. Furthermore, numerous blood vessels and nerves were located: the optic nerve surrounded by the retractor bulbi muscle; the superficial temporal artery and vein adjacent to the temporal muscle; the deep lingual artery and vein in the root of the tongue; the mandibular nerve; and the maxillary artery, vein, and nerve situated mediodorsal to the pterygoid muscle. The various cranial bones surrounding the brain were identified, including the parietal and interparietal, pterygoid, temporal, basisphenoid, presphenoid, and occipital bones. Parts of the mandible and the hyoid bone could also be seen.

On the CT images without contrast material from the other 3 dogs, most parts of the brain and almost all bony, muscular, nervous, and vascular structures mentioned were similarly visible. In 2 dogs, a large amount of CSF was present in the ventricular system, which made it possible to locate the rostral and caudal colliculi on the images. The third dog had a small amount of CSF; therefore, it was rather difficult to identify the ventricles, infundibular recess, mesencephalic aqueduct, and the subarachnoid space. In the same dog, the superficial temporal arteries and veins and the internal carotid arteries could not be identified via CT. In 1 of the other dogs, the maxillary vein and artery could not be located with certainty. The falx cerebri and the longitudinal cerebral fissure were not distinct in images from 1 dog and the canal of the transverse sinus was not identifiable in

images from another. The alar canal and the cochlea could not be seen in images from any of the 3 dogs.

On evaluation of the CT images of the 4 dogs obtained after administration of contrast material, only the falx cerebri and the blood vessels were more distinct, compared with the images obtained before administration of contrast material (not shown).

DISCUSSION

The present investigation was carried out to characterize the anatomic features of the brain of clinically normal dogs by use of a high-resolution CT system. In our study, dolichocephalic dogs were used. In a previous study,⁴⁷ small interbreed variations of anatomic structures, such as the size of the ventricles or depth of the hypophyseal fossa, as well as important individual variations among dogs of the same breed, have been described.

Numerous structures of the canine brain identified on anatomic sections were also identified on the CT images. For best contrast resolution of the CT images, the window width should be narrow and the window level should be set at a number similar to the mean Hounsfield units of the structure of interest. However, the distinctions among internal brain structures were frequently difficult because of the minor density differences on CT images; therefore, landmarks such as hypodense CSF and bony structures were used for orientation, and standard anatomic texts were used for reference.⁴¹⁻

^{45,47-49} The presence of CSF in the ventricles and in the subarachnoidal space facilitated the accurate identification of various adjacent structures and tissues that were not discernible on the basis of their appearance or inherent density alone. In 2 dogs of the present study, a relatively large amount of CSF was present; consequently, identification of adjacent structures, such as the caudate nucleus, rostral and caudal colliculi, corpus callosum, fornix, geniculate bodies, hippocampus, mamillary body, rostral commissure, septum pellucidum, thalamus, and interthalamic adhesion, was easier in these images than in the images from the other 2 dogs. In addition, numerous bony landmarks present on the CT images (eg, the osseous tentorium cerebelli, falx cerebri, dorsum sellae turcicae, and chiasmatic sulcus, along with bony foramina and canals) facilitated the identification of important intracranial structures such as the cerebral peduncles and lobes,

transverse and longitudinal cerebral fissures, hypothalamus, hypophysis, olfactory peduncle and tract, optic chiasm and nerve, and pons.

Administration of contrast material can be an important part of CT investigations, although it does not necessarily need to be performed in every situation.¹¹ The use of contrast medium enhances the CT visualization of certain clinically normal brain structures such as the pituitary gland,⁴⁸ falx cerebri, and some blood vessels. It is also effective as a high-contrast marker of pathologic changes of the brain, which is especially useful for the diagnosis of brain tumours.^{1,2,4-6,9,10,12-14,16,18,20,22,24-26,28-31,33} However, even after administration of contrast, a number of intracranial mass lesions may not be detectable by means of CT, probably because of their diffuse distribution, similar attenuation to surrounding tissue, and minimal or absent contrast enhancement.¹⁵

It is known that magnetic resonance imaging (MR) provides superior soft tissue detail, compared with that achieved by CT, and allows visualization of subtle changes that accompany diffuse brain lesions that are not easily detected via CT.¹⁵ Also, MR is preferred for imaging structures at the caudal cerebral fossa because these are frequently poorly defined on CT images; this is caused by streak artefacts that are a result of beam hardening in this region.¹¹ The multiplanar imaging capability of MR permits a better definition of the anatomic relationship of an intracranial lesion and surrounding unaffected structures.¹⁵ However, by use of advanced computer software, it is possible to use original display data to reform CT images in dorsal and sagittal planes,⁴⁴ thereby obtaining a 3-dimensional presentation of anatomic features. Visualization of specific morphologic components can be optimized in these multiplanar CT images by varying the CT window and level settings. The combination of multiplanar imaging and selective viewing constitute a unique and flexible means of brain imaging in dogs.⁴⁴ If MR is not available, CT is an extremely useful diagnostic procedure in dogs in which intracranial disease is suspected. Because a thorough knowledge of the anatomic features of the brain in clinically normal dogs is a prerequisite for accurate interpretation of CT images in which pathologic changes may be evident, the comprehensive iconography provided in the present study may be a useful tool for diagnosis of neuropathologic conditions of the brains of dogs.

**1.1.2. Magnetic Resonance imaging
of the Normal Canine Brain**

Lieve M. De Rycke, DVM

Department of Medical Imaging, Faculty of Veterinary Medicine,
Ghent University, Salisburylaan 133, 9820 Merelbeke, Belgium

SUMMARY

Objective—To provide a detailed anatomic description of brain structures in clinically normal dogs by means of magnetic resonance imaging (MR).

Animals—1 clinically normal adult German Shepherd Dog weighing 30 kg.

Procedure—Immediately after the CT examination of the brain (*see chapter 1.1.1.*) and under the same anesthesia, MR of the brain was performed in one of the German shepherd dogs. The animal was kept in the same position as used on the CT scanning table (dorsal recumbency with the forelimbs extended caudally). Transversal T1-weighted weighted (repetition time (TR) = 498msec, echogenicity time (TE) = 14msec) and T2-weighted images (TR = 7820msec, TE = 104msec) were obtained with a slice thickness of 4 mm, extending from the cribriform plate of the ethmoid bone to the cranial part of the atlas and perpendicular to the hard palate, on a 1.5 closed Tesla MR unit ^a. For this study only the T1-weighted images were used as a good anatomical resolution was most important. After euthanasia, anatomic sections were performed (*see chapter 1.1.1*) and compared with the corresponding MR views. Subsequently the CT images of the previous study (*chapter 1.1.1*) were compared to the MR images.

Results—A lot of brain structures that were visible on the anatomic sections could be identified on the MR images. When comparing the MR images of the brain with the corresponding CT images (*Figure 2, chapter 1.1.1*), all brain structures and surrounding soft tissue structures identified on the CT images could be much better visualized on the MR images and several additional brain structures were located on the MR images. Only the bony structures of the skull were more distinct on the CT images compared to the MR images.

Conclusions and Clinical Relevance—MR is a non-invasive technique that provides anatomic detail of numerous structures of the canine brain. These results could be used as a basis for evaluation of MR images of the brain of dogs with pathologies of the CNS.

INTRODUCTION

In humans, MR is frequently used for imaging the CNS. This technique has the ability to produce high-detail, high-contrast, two-dimensional grayscale images of the brain, on a non-invasive way and without ionising forms of electromagnetic energy. Consequently, the complex anatomy of the head and brain is better defined with MR than with conventional radiology, scintigraphy or computed tomography (CT)¹. The superior contrast resolution of soft tissue provided by MR facilitates diagnosis of many CNS lesions, including tumors and other degenerative abnormalities¹.

MR has been increasingly used in veterinary medicine during the last decade. The majority of publications on MR of the brain concern clinical reports of dogs and cats with neurologic disease²⁻³³, and MR studies of brain structures such as the ventricles³⁴⁻³⁹ and the pituitary gland⁴⁰.

A few publications on MR anatomy of the normal brain are available. One paper reports the MR of the brain of normal neonatal foals¹ and two others describe the MR of the normal feline brain^{41,42}. MR anatomy of the canine brain has been described by one research team⁴³ and an atlas of MR of the dog has recently been published⁴⁴. However, to date a detailed comparative study using gross anatomic sections to identify all structures visible on MR images of the canine brain has not been reported. Knowledge of normal MR anatomy of the canine brain is a prerequisite for MR diagnosis of abnormalities.

The purpose of this study was to determine normal canine MR neuroanatomy and to make a comparison with corresponding CT images (*Figure 2, chapter 1.1.1*).

MATERIAL AND METHODS

Immediately after the CT examination of the brain (*see chapter 1.1.1*) and under the same anesthesia, MR of the brain was performed in one of the German shepherd dogs used in the previous study. The animal was kept in the same position as used on the CT scanning table (dorsal recumbency with the forelimbs extended caudally). Transverse T1-weighted weighted (repetition time (TR) = 498msec, echogenicity time (TE) = 14msec) and T2-weighted images (TR = 7820msec, TE = 104msec) were obtained with a slice thickness of 4 mm, extending from the cribriform plate of the ethmoid bone to the cranial part of the atlas and perpendicular to the hard

palate, on a 1.5 closed Tesla MR unit ^a. Acquisition matrix was 256 x 256. For this study only the T1-weighted images were used as a good anatomical resolution was most important.

The anatomical sections of the brain (*see chapter 1.1.1.*) were compared with the corresponding transverse MR images. From the collection of matched MR and anatomical images, 13 representative pairs were selected from the rostral to the caudal regions of the brain (*Figure 2 chapter 1.1.1*). The structures identified on the anatomical sections (*see chapter 1.1.1*) were subsequently located on the corresponding MR images.

Afterwards a comparison with the corresponding CT images of the brain was made.

RESULTS

Most of the brain structures that were visible on the anatomic sections could be identified on the MR images, except for some parts of the diencephalon such as the epiphysis, hypophysis with infundibulum and the mamillary body, probably because these structures were not present in one of the sections. The mesencephalic red nucleus and substantia nigra could not been located on the T1-weighted MR images, neither the cerebellar white matter.

When comparing the MR images of the brain with the corresponding CT images (*Figure 2 chapter 1.1.1*), all brain structures and surrounding soft tissue structures identified on the CT images could be much better visualized on the MR images. Moreover several brain structures such as the internal capsule, optic tract, hippocampal gyrus, rostral and caudal collicle, interpeduncular fossa, brachium of the pons, median ventral fissure, floccular lobe, pyramid of the medulla oblongata and the choroid plexuses of the fourth and lateral ventricles could easily be located on the MR images and were unidentifiable on the CT images. Only the bony structures of the skull especially foramina, fossae, canals and the chiasmatic sulcus, were more distinct on the CT images compared to the MR images.

These results are listed in Table 1.

TABLE 1 : Structures of the canine brain and surrounding structures visible on CT and MR scans

+ = identified, -- = not identified, N = not present on the figures

CONCLUSIONS

MR is a non-invasive technique that provides anatomic detail of numerous structures of the canine brain. The surrounding soft tissue structures of the head such as the muscles, blood vessels and some nerves are also distinct and can easily be identified. On the T1-weighted images fat tissue and bone marrow generate a high signal, whereas muscle and other soft tissue (glands, nerves, brain-parenchyma) demonstrate an intermediate signal. The white matter signal is slightly more hyperintense compared to the signal of the grey matter. Vascular structures, CSF and air show a signal void. Only the bony structures of the skull, which show a signal void on MR images, could be better visualized on the CT images.

The conclusion is that MR provides more details of the brain parenchyma, especially at the caudal cerebral fossa, than CT. Therefore it is the technique of preference in case of brain pathologies. Only if MR is not available, CT can be of useful when intracranial disease is suspected. These results could be used as a basis for evaluation of MR images of the brain of dogs with pathologies of the CNS.

SUMMARY

Objective- To use computed tomography (CT) and magnetic resonance imaging (MR) to provide a detailed description of the nasal cavities and paranasal sinuses in clinically normal mesaticephalic dogs.

Animals- Two clinically normal Belgian Shepherd dogs weighing 25 and 35 kg, respectively.

Procedure- The first dog was anesthetized and positioned in ventral recumbency for CT and MR examinations, and transverse slices were obtained from the caudal part of the frontal sinuses to the nares. For MR, T1-weighted, T2-weighted and proton density sequences were obtained. The second dog was anesthetized and positioned in dorsal recumbency with the head perpendicular to the table, and CT and MR examinations were again conducted. At the completion of the MR examination, each dog received an intravenous (IV) injection of heparin and then was euthanatized. A 4% solution of formaldehyde was perfused IV immediately after each dog was euthanized. The skull was prepared, decalcified, embedded with gelatine, and sectioned into 5-mm-thick sections by use of a stainless steel knife. Each anatomic section was photographed and compared with the corresponding CT and MR views.

Results- Structures on the CT and MR views matched with structures on the corresponding anatomic sections. The CT scans provided good anatomic detail of the bony tissues, and MR scans were superior to CT scans for determining soft tissue structures.

Conclusions and Clinical Relevance- CT and MR provide a means for consistent evaluation of all structures of the nasal cavities and frontal sinuses. Both techniques could be useful for evaluation of diseases that affect the nasal region such as fungal rhinitis, nasal tumors, non-specific rhinitis and foreign body rhinitis.

INTRODUCTION

Computed tomography (CT) and magnetic resonance imaging (MR) are reliable noninvasive techniques for use in the diagnosis of nasal diseases in dogs.^{1,2} These techniques have been used in dogs with fungal rhinitis, nasal tumors, non-specific rhinitis and foreign body rhinitis.^{1-9,a}

CT and MR are superior to radiography for defining the extent and character of lesions in the nasal cavities.^{3,6,8,10-12} In addition, these techniques are also useful for staging of tumors and during planning for surgery and radiation treatments; they also have a prognostic value in dogs with nasal aspergillosis.^{5,13-15}

In the veterinary literature, there is paucity of publications on the use of CT and MR for determining anatomy of the head of animals. In one report,¹⁶ CTscans of the normal nasal cavities and paranasal sinuses of cats were described, whereas MR views and the cross sectional anatomic features of the normal sinuses and nasal passages of horses were reported in another study.¹⁷ CT scans of the anatomy of the head of dogs have been described¹⁸⁻²³ and an atlas of MR and CT views of dogs has been published²⁴. However, to our knowledge, a detailed comparative study of gross anatomic sections to identify all structures visible on CT and MR scans of the nasal cavities and paranasal sinuses of dogs has not been conducted.

Thus, the objective of this study was to provide a comprehensive atlas of the normal nasal cavities and paranasal sinuses in dogs by use of CT and MR.

MATERIAL AND METHODS

Animals - Two healthy Belgian Shepherd Dogs that weighed 25 and 35 kg, respectively, were used in the study. Neither dog had a history of nasal disease, and pathologic conditions were not detected during physical and radiographic examinations. Four radiographic images were obtained for each dog (dorsoventral and lateral radiographs of the entire skull, dorsoventral intraoral radiograph of the nasal cavities and maxilla, and rostrocaudal radiograph of the frontal sinuses).

CT and MR– Dogs were sedated by IV administration of fentanyl (0.005 to 0.01 mg/kg) and droperidol^b (0.25 to 0.5 mg/kg) Anesthesia was induced by IV administration of thiopental sodium^c

(8 mg/kg). Dogs were intubated and anesthesia was maintained by administration of halothane^d 1.5-2%. The CT and MR examinations were then performed on the anesthetized dogs.

The first dog was positioned in ventral recumbency for CT and MR examinations, and transverse slices of the nasal cavities and paranasal sinuses were obtained. First, CT was performed by use of a third generation CT scanner^e. Technical settings were 120 kV and 130 mA. Five-millimeter-thick contiguous slices were obtained from the caudal aspect of the frontal sinuses to the nares and perpendicular to the length-axis (or hard palate) of the skull. Hard copies were printed^e by use of a bone setting (window width = 3,500 Hounsfield units; window level = 500 Hounsfield units).

Immediately after CT was completed, MR was performed using commercially available equipment^g. A series of 5-mm transverse slices was obtained from the caudal aspect of the frontal sinuses to the nares. The T1-weighted (repetition time (TR) = 400msec, echogenicity time (TE) = 19msec), T2-weighted (TR = 4000msec, TE = 80msec) and proton density (TR = 4000msec, TE = 18msec) images were acquired. Acquisition matrix was 256 x 224.

The second dog was positioned in dorsal recumbency with the head perpendicular to the table; this dog was used to obtain dorsal (i.e., horizontal) images from the nasal cavities and paranasal sinuses. The same CT and MR protocol was used in both dogs.

Comparison of CT and MRI images and anatomic structures - At the completion of the MR examination, each dog was injected IV with heparin (via a cephalic vein). The dogs were then euthanatized.

A 4% solution of formaldehyde was perfused IV (via a jugular vein) immediately after each dog was euthanatized. The head of each dog was removed at the atlanto-occipital joint, and the skin of the cranium, mandibles, and temporal muscles were removed. Each skull was placed in a nitric acid solution for decalcification for 2 weeks; skulls were then embedded with gelatin. Each skull was sectioned into 5-mm-thick sections by use of a stainless steel knife. Each anatomic section was photographed and compared with the corresponding CT and MR views. From this collection, 11 (9 transverse and 2 dorsal) representative matched series of images of the nasal cavities and paranasal sinuses were selected from rostral to caudal (9) and dorsal to ventral (2) regions. Bony structures and soft tissues were identified on the anatomic sections. The identified structures were subsequently located on the corresponding CT and MR views. Nomenclature used for designating all structures was in accordance with official anatomic terms.²⁶

RESULTS

Nine representative transverse planes extending from the olfactory bulb of the brain to the alar cartilage were selected in the first dog, and 2 dorsal planes of the nasal cavities were selected in the second dog (Fig 1). CT and MR (T1-weighted, T2-weighted and proton-density sequences) scans of the nasal cavities were compared with the corresponding anatomic sections (Figs. 2 and 3).

Figure 1 – Lateral computed tomography CT scans of transverse (a) and dorsal (b) views of the nasal cavities and paranasal sinuses of 2 clinically normal mesaticephalic dogs indicating the location (A through K) at which the anatomic sections, CT scans and magnetic resonance scans (MR) were obtained.

Most parts of the nasal cavities and paranasal sinuses could be identified on the anatomic sections. Several adjacent structures that remained on the skull, such as the olfactory bulb of the brain, orbits, canine teeth, nasopharynx, soft palate, salivary glands, and pterygoid muscles were quite distinct. The various facial bones that form the wall of the nasal cavities as well as the nasal conchae, septa, meatuses and all endo- and ectoturbinate could easily be identified. The medial and lateral parts of the frontal sinuses and the maxillary recess were also visible.

On the CT scans it was also possible to identify various structures of the nasal cavities and paranasal sinuses. Only the dorsal, middle and ventral nasal meati and some of the ectoturbinate could not be located. We were also less able to distinguish several surrounding soft-tissue structures on the CT scans such as the different parts of the eye, the pterygoid muscle, the zygomatic salivary gland and the falx cerebri.

It was difficult to identify facial bones on the MR scans, but most of them could be located due to their void signal. In contrast, the conchae, conchal septa, and turbinates were easy to see because of the distinct mucosal covering. Only some of the ectoturbinates could not be identified. The surrounding soft-tissue structures were clearly visible on MR scans, especially when compared to the CT scans.

Figure 2 – Transverse anatomic sections (upper left), CT scans (lower left), and MR scans (T1-weighted MR (top right), T2-weighted MR (middle right), proton density (bottom right)) of the nasal cavities and paranasal sinuses of clinically normal mesaticephalic dogs. Images were obtained at sections A through I as illustrated in figure 1.

DISCUSSION

Although information on CT and MR scans of the nasal cavities and frontal sinuses of dogs exists^{18,19,24}, a detailed anatomic description of those images in clinically normal dogs is lacking. The complexity of radiographs attributable to superimposition of the facial bones and the nasal turbinates can be overcome by use of single-plane images of the nasal cavities and frontal sinuses. Images through the transverse, dorsal, or sagittal plane provide detailed anatomic information. The sagittal plane was not used in this study because it does not permit symmetric comparison between the left and the right sides of the nose. The dorsal plane is most appropriate for use in determining the integrity of the cribriform plate in dogs with nasal tumors or nasal aspergillosis.¹¹ Images through the dorsal plane also provide a more general view of the entire nasal cavities, allowing easier characterization of the disease processes. This differentiation is also possible by use of

transverse images obtained via the transverse plane. Moreover, images for the transverse plane can easily be obtained with a dog positioned in ventral recumbency, and this allows better evaluation of the nasal turbinates, which is essential for the diagnosis of diseases that affect the nasal region. Therefore, the transverse plane is the reference plane for the assessment of nasal pathologic changes.

MR allows investigators to make multiplanar images without repositioning the dog.²⁸ It is also possible to obtain dorsal, sagittal and transverse views of the same dog by use of CT, but this requires repositioning of the dog, which may be complicated. An alternative method to achieve CT images in various planes without repositioning the dog is by way of dorsal and sagittal reconstructions, although their quality on a third generation scanner is inferior to that of native images. Recent multidetector helical CT scans are capable of producing isotropic voxels, and multiplanar reconstructions are therefore of the same high quality as the original transverse images.

The CT examinations were reviewed only using bone window settings. The nasal cavities and paranasal sinuses do not contain soft-tissue structures other than the mucosa.¹⁹ Therefore, a soft-tissue window was not used in our anatomic study. A soft-tissue window in combination with examinations conducted by use of contrast agents, may be useful in nasal cavity with pathologic changes to enable differentiation between fluid and soft tissue or to define more accurately the nature of an abnormal soft-tissue structure.^{8,12} However, in pathologic conditions, the nasal cavities often contain many structures of different physical densities (ie, bone, cartilage, mucosa, and air) which makes most CT measurements of attenuation values unreliable.^{7,27} In contrast to CT, MR allows differentiation between the nasal mucosa and other soft tissues or fluid.

Analysis of results of the study reported here indicates that all nasal structures can be evaluated by use of CT or MR. However, differentiation between the various layers of the nasal mucosa is not possible with these techniques.

CT and MR are increasingly available to veterinarians. Axial CT, MR and radiography require at least 15 minutes for a complete examination and must be performed in anesthetized animals. Using helical CT, the time of the examination is considerably reduced (2 to 4 minutes), and the procedure may be performed in animals that are deeply sedated.²⁶ Advantages of CT over MR include lower cost and a reduced amount of time to conduct an examination. Advantages of MR over axial CT include the use of multiplanar capabilities.

The information reported here should serve as a baseline reference for evaluation of CT and MR scans of the nasal cavities and paranasal sinuses of dogs. It can be used to assist in interpretation of pathologic conditions of the nasal region.

SUMMARY

Objective—To provide a detailed anatomic description of the thorax in clinically normal dogs by means of computed tomography.

Animals—4 clinically normal adult German Shepherd dogs weighing 28 to 37 kg.

Procedure—Dogs were anesthetized and positioned in ventral recumbency for computed tomographic (CT) examination of the thorax. A CT image from the thoracic inlet to the diaphragm was made by use of a third- generation scanner with a slice thickness of 5mm. Individual images were reviewed by use of soft tissue (mediastinal)(window width, 250 Hounsfield units; window level, 35 Hounsfield units) and lung (window width, 1000 Hounsfield units; window level, -690 Hounsfield units) settings. One dog, weighing 28 kg, was euthanatized, bound on a wooden frame in the same position as used for CT examination, and frozen at -14°C until solid. By use of an electric band saw, the frozen thorax was sectioned at 10-mm thick intervals. Slab sections were immediately cleaned, photographed, and compared with corresponding CT images.

Results—Anatomic sections were studied and identified anatomic structures were matched with structures on corresponding CT images. Except for some blood vessels and parts of the heart, most of the bony and soft tissue structures of the thorax discerned on anatomic slices could be found on matched CT images.

Conclusions and Clinical Relevance—Because CT images provide detailed information on most structures of the canine thorax, results of our study could be used as a guide for evaluation of CT images of dogs with thoracic diseases.

INTRODUCTION

Computed tomography (CT) of the thorax has become established as an important radiologic procedure. CT displays of the lungs, mediastinum, pleural cavity, and chest wall in a transverse plane provide unique diagnostic information that is unobtainable with conventional radiographic techniques.¹ Compared with conventional radiography, CT allows better distinction among specific tissue densities in the thorax and detection of subtle changes in organ size, shape, margin contour, and position.²⁻⁴

In human medicine, use of CT plays a key role in the diagnosis and evaluation of various thoracic syndromes and diseases such as pneumothorax; pleural and pericardial effusion; collapse of a lung lobe; congenital anomalies; pulmonary parenchymal and bronchial diseases; cysts; abscesses; and primary or metastatic neoplasia of the lungs, pleura, mediastinum, lymph nodes, and chest wall.^{1,5-23} Furthermore, CT is a useful preoperative technique, a precise staging tool, and improves the use of biopsies by allowing detection of lesions not identifiable by fluoroscopy and determination of the location of high-risk masses that are close to cardiovascular structures.^{24,25,a}

The use of CT in diagnosing thoracic diseases in veterinary medicine is in full exploration,^{4,26-35} and an increasing number of published clinical reports^{3,36-40} are found involving thoracic CT. Accurate interpretation of CT images of the thorax requires a thorough knowledge of cross-sectional anatomy of that region. A few papers^{41,42} on CT anatomy of the thorax of clinically normal animals are available. Authors of one paper⁴¹ described the CT and cross-sectional anatomy of the thorax of clinically normal cats and authors⁴² of another paper reported the CT anatomy of the thorax of Nubian goats. The purpose of the study reported here was to identify structures that are visible on CT images of the canine thorax by means of a detailed color atlas consisting of a series of labeled anatomic photographs. Although some publications^{2,43-46} on cross-sectional CT anatomy of the canine thorax exist, in the present study we combined the study of CT and gross anatomic sections, which provides more detailed and additional information.

MATERIAL AND METHODS

Animals—Four clinically normal adult German shepherd dogs weighing 28 to 37 kg were used for this study. Before the onset of CT examination, a clinical and radiographic examination of the thorax of each dog was performed, which included obtaining right and left lateral radiographic views of the thorax.

Computed tomography—Dogs were sedated by use of medetomidine hydrochloride^b (40 to 50 µg/kg of body weight, IM), and anesthetized with thiopental sodium^b (8 mg/kg, IV). After intubation, anesthesia was maintained with 1.5% to 2% halothane^d. Intermittent positive-pressure ventilation was applied to the lungs to decrease motion artifacts caused by irregular or fast respiration of the dogs. Respiratory rate was set at 6 breaths/minute.

Dogs were positioned in ventral recumbency on the scanning table with forelimbs in extension. A lateral survey view was made by use of a third generation CT scanner^e. Transverse, 5mm thick contiguous CT images of the thorax from the thoracic inlet to diaphragm were obtained. Settings for the CT image technique were 120 kV and 100 mA. Hard copies were printed^f on x-ray film by use of a soft tissue setting (window width, 250 Hounsfield units; window level, 35 Hounsfield units) and a lung setting (window width, 1000 Hounsfield units; window level, -690 Hounsfield units).

Comparison of CT and anatomic images—At the end of CT examination 1 dog weighing 28 kg was euthanatized for reasons unrelated to thoracic disease. For euthanasia a combination^g of embutramide, mebenzoniumiodide, and tetracaïne (0.3 ml/kg of body weight) was injected IV during anesthesia. After euthanasia, the dog was bound on a wooden frame in the same position used for scanning and frozen at -14°C until solid. The frozen cadaver was placed on the movable table of an electric band saw^h, and serial transverse sections were cut approximately 10 mm apart, beginning at the thoracic inlet and ending at the diaphragm. Slices were numbered and gently cleansed of debris with cold tap water and light brushing. They were immersed in water, and the cranial surface of each section was photographed immediately (ie, before thawing). Photographs were studied, and identifiable anatomic structures were labeled with the aid of texts on canine anatomy.^{47,48} For each anatomic slice, a corresponding CT image was chosen on the basis of similar appearance. Identified structures were subsequently located on CT images. Nomenclature

used for designating all structures was in accordance with official anatomic terminology.⁴⁹ From this collection, 24 representative matched pairs of images extending from the level of the sternal manubrium to the most caudal part of the lungs were selected.

RESULTS

The 24 selected levels, at which anatomic sections and their corresponding CT images were made, are indicated on a lateral survey view of the thorax of a German Shepherd (Figure 1). Identifiable anatomic structures are labeled on cadaver sections and corresponding CT images (Figure 2).

Figure 1—Lateral computed tomographic (CT) survey pilot image of the thorax of a clinically normal dog indicating the levels (A through X) at which the CT images were obtained.

On anatomic sections various structures of the canine thorax could be identified. Respiratory tract structures including the trachea, tracheal bifurcation (with carina), principal bronchi, lobar bronchi, and various lobes of the left and right lungs were clearly visible.

Large vessels such as left and right external jugular veins, brachiocephalic veins, common carotid arteries, subclavian and axillary arteries and veins, costocervical trunks and veins, and the cranial vena cava could readily be seen in the cranial mediastinum. Identification of these vessels could be ascertained by comparing cross-sectional images on successive levels. Other intrathoracic vascular structures including the thick walled aortic arch, ascending and descending aorta, pulmonary arteries and veins (located ventral to corresponding principal bronchi), left coronary artery, internal thoracic arteries and veins ventral to the transversus thoracis muscle, right azygos vein (located

dorsal to the esophagus), intercostal veins, vertebral arteries and veins within the transverse canals, and the prominent caudal vena cava were observed.

Intrathoracic structures such as the heart with its chambers and valves, esophagus, longus colli muscle, and transverse thoracic muscle could easily be distinguished. Sternal lymph nodes were identified ventral to the transversus thoracis muscle and dorsal to the manubrium of the sternum. Cranial mediastinal lymph nodes were discerned lateral to the cranial vena cava. Tracheobronchial lymph nodes could be observed ventral to the tracheal bifurcation.

Various parts of the thoracic wall including the sternum, ribs with the intercostal muscles, and thoracic vertebrae enclosing the spinal cord were clearly visible. Other identifiable structures were the scapulae, nuchal ligament, and muscles of the thorax and proximal part of the forelimbs. In caudal sections the liver with portal and hepatic blood vessels, gallbladder, stomach, cranial and descending duodenum, and diaphragm could be discerned.

In the 4 dogs examined most of the previously mentioned structures of the thorax could be identified on CT images at the soft tissue setting. The heart silhouette could be observed, but cardiac chambers, valves, and interventricular septum were not visible.

In any dog, the nuchal ligament, left coronary artery, intercostal veins, vertebral vessels, lobar bronchi, and various lobes of the lungs could not be distinguished. In the cranial mediastinum, the left and right axillary arteries and right costocervical trunk and vein could not be discerned. Furthermore, portal and hepatic vessels, diaphragm, and descending duodenum were not visible in the most caudal CT images of the 4 dogs. The left costocervical trunk and contours of the gallbladder could be discerned in 2 of the 4 dogs. The ascending aorta, left costocervical vein, left and right axillary vein, main bronchus of the accessory lobe of the right lung, and left and right pulmonary veins could be identified in 3 of the 4 dogs by comparing their position on the corresponding anatomic images. In all 4 dogs most parts of the stomach could be seen.

On CT images obtained at the lung setting, only various structures of the respiratory tract and some large vessels were distinct in all dogs. The tracheobronchial tree including the trachea, tracheal bifurcation, principal bronchi, lobar bronchi, and various lobes of the left and right lung could easily

be discerned. In 1 dog, however, the lobar bronchus of the accessory lobe of the right lung could not be discerned. Large intrathoracic vessels such as the descending aorta, caudal vena cava, and major pulmonary arteries and veins could be identified in all instances. Of the heart and liver only contours were visible. The presence of air in the esophagus and in cardia and fundus of the stomach allowed the position of these organs to be determined on CT images. However, it was impossible to see the cardiac sphincter and all parts of the stomach in any dog.

DISCUSSION

Results of our study indicate that the use of anatomic sections is helpful for identifying a large number of thoracic structures that are visible on CT images of the canine thorax. Only nerves and small vessels could not be discerned. Anatomic images made in our study matched closely with corresponding CT images, except for the more caudal position of the scapulae on CT images. This indicates that the forelimbs were less extended during CT examination than during the freezing process.

Dogs are routinely positioned in sternal (ventral) recumbency to prevent recumbency-induced pulmonary atelectasis.^{4,27,30} Dogs with severe hydrothorax are scanned twice; once in ventral recumbency and once in dorsal recumbency.²⁷ For a complete examination of the lungs, it is recommended to scan the patient in various positions, depending on the area of interest, because atelectasis and gravitational pulmonary-flow differences may alter the density of the dependent lung. Assisted suspended inspiration may also be needed to better assess overall lung density.³²

Thoracic CT images were evaluated by use of a lung and a soft tissue (mediastinal) setting. A lung window consists of a broad window width (1000 to 2000 HU) centered around a negative value (-600 to -700 HU). This allows the lung parenchyma to appear gray. A mediastinal window consists of a narrow window width (300 to 400 HU) centered on soft tissues (40 to 50 HU).³² Various structures of the respiratory tract were most distinct on the lung window. Still, for detection of pathologic processes, the lungs should be evaluated with lung and mediastinal windows to avoid missing lesions excluded by window settings.³²

In our study the various parts of the heart could not be identified on soft tissue CT images and the details of the lungs could not be defined on lung window CT images as a result of motion artifacts.

Because thoracic CT investigations were performed on living dogs, cardiovascular movements could not be avoided. Applying intermittent positive-pressure ventilation to the lungs decreased motion artifacts caused by irregular or fast respiration of each dog. Computed tomographic images were taken during the expiratory pause of dogs as described by Henninger et al.²⁹ Hyperventilation is another method that has been described for decreasing respiratory movements during performance of intrathoracic biopsies.²⁵ Use of newer scanning equipment such as helical (spiral) computed tomography, could also minimize these motion artifacts.^{2,19,20,30,32} In the past few years, high-resolution computed tomography (HRCT) has been found useful for evaluation of the lungs and for diagnosis of a variety of pulmonary diseases.^{9,15,18,30,32,50} HRCT allows structures as small as 0.2mm to be visualized, gives a detailed display of lobular and sublobular anatomy and allows a better assessment of parenchymal detail than conventional CT. However the examination time is long and the radiation burden inherent in HRCT is considerable. Therefore, conventional CT of the lungs should still be used for routine indications and HRCT should be reserved for particular circumstances.¹¹

Until now some information has been published^{3,27,29,30,32} on the use of computed tomography for pulmonary evaluation in animals. Nevertheless, applications of pulmonary computed tomography in dogs and cats appear to be similar to those in humans and the role of computed tomography for diagnostic and investigative studies of the heart and lungs will likely progress as access to better equipment improves.³²

A number of vessels identified on anatomic sections could not be discerned on corresponding CT images. Intravascular administration of contrast media might be helpful in identification of vascular structures on soft tissue CT images.²⁹ In humans, computed tomography following an IV bolus of contrast medium has replaced arteriography for the diagnosis of most intrathoracic vascular lesions.¹¹ Intravascular contrast agents are also useful in defining the extent of mediastinal masses and their relation to delicate structures such as major vessels or the heart and to enhance the pleura.^{4,21,29,32} Intravenous contrast enhancement of the heart allows the atria and chambers to become readily visible and a rough estimation of chamber wall thickness can be made.²⁹ Subsequently a definitive diagnosis of pericardial effusion becomes also possible.²² In our study, IV administration of contrast medium was not used because the aim was to describe plain CT images made by standard procedures.

Thoracic CT is more and more routinely used in veterinary medicine. In the future its use in animals as a diagnostic and preoperative tool for detection of thoracic diseases and as a guide for

performing thoracic biopsies will undoubtedly still evolve.¹ Results of our study indicate that CT images provide detailed information on most structures of the canine thorax. Therefore our description of CT anatomy of the canine thorax could be used for evaluation of CT images of dogs with thoracic disease.

SUMMARY

In four healthy, adult male German shepherd dogs, thoracoscopy was performed to provide a detailed description and illustration of the endoscopic anatomy of the normal intrathoracic structures of dogs. The dogs were anesthetized and placed in left or right lateral recumbency. The cannula and the endoscope were advanced into the thoracic cavity via entry of the free upper side in the dorsal third of the eighth intercostal space. Most intrathoracic structures of the left and right hemithorax were endoscopically visible. During the four thoracoscopic procedures, endoscopic photographs were taken and are illustrated in this paper.

A sound knowledge of the anatomy of intrathoracic structures is a prerequisite for diagnostic and therapeutic thoracoscopy.

INTRODUCTION

Thoracoscopy is an accurate and practical technique for diagnosis and surgical management of intrathoracic pathologies. The technique is minimally invasive and allows a rapid postoperative recovery. Disadvantages are the expensive equipment and the need for technical training of the surgeon. Contraindications to thoracoscopy are profuse bleeding and hemodynamic instability.

In human surgery, thoracoscopy is a rapidly expanding area. It is used for diagnosis of diseases and traumatic injuries involving the pleura, lungs, esophagus, heart, pericard, diaphragm, lymph nodes and vertebrae¹⁻⁵. Biopsies of lungs and lymph nodes, for diagnosis of diffuse lung diseases or for staging of lung cancer, can be taken under thoracoscopic guidance. Thoracoscopic biopsies are also possible for extrapulmonary tissues such as vertebral bodies, thoracic wall and mediastinal masses, and pleura⁶⁻⁸.

Thoracoscopy is not only a diagnostic tool, but can also be used for minimal invasive thoracic surgery such as lung lobectomy or lung wedge resection in cases of lung disease, neoplasia and bullae (bullectomy); drainage of empyema, hemothorax and spinal abscesses; esophageal myotomy or esophagectomy in case of neoplasia; fenestration of the pericard or pericardectomy in case of pericardial effusion; ligation of patent ductus arteriosus and vascular ring-anomaly; thymectomy in the setting of myasthenia gravis; resection of benign thymic, pericardial and bronchogenic cysts; resection of neurogenic mediastinal tumors; sympathectomy in case of palmar hyperhidrosis and parietal pleurectomy in case of malignant pleural effusion⁸⁻²³. Thoracoscopy is also used for surgical treatment of traumatic thoracic injuries; diaphragmatic hernia; bronchopleural fistulas; chylothorax; spontaneous pneumothorax and herniated intervertebral discs^{3,5,24-26}.

Until now, the application of the technique in veterinary medicine is limited to experimental studies and direct observation of the pleural cavity and intrathoracic structures, collection of pleural fluid, repair of diaphragmatic hernias, and obtaining of biopsy specimens of lungs in horses²⁷⁻³⁰ and dogs³¹⁻³⁶. Some surgical interventions by means of thoracoscopy have been reported in dogs including ligation of the thoracic duct, correction of persistent right aortic arch, pericardectomy, lung lobectomy, ligation of a patent ductus arteriosus, and fenestration of thoracic intervertebral discs³⁷⁻⁴⁸. There is still much to learn about indications, side-effects, advantages, disadvantages,

complications and contraindications of veterinary thoracoscopy. Moreover, before performing thoracoscopy a good knowledge of the intrathoracic anatomy is required.

The purpose of the present study was to describe and illustrate the endoscopic anatomy of the normal intrathoracic structures in four healthy dogs.

MATERIALS AND METHODS

Thoracoscopy was performed on 4 adult, male, clinically healthy Shepherd dogs owned by the University of Ghent, Faculty of Veterinary Medicine, Department of Medical Imaging. The animals weighed between 25 and 33 kg.

The animals had fasted for 12 to 24 hours prior to the procedure. After positioning the dogs in left (n=2) or right (n=2) lateral recumbency thoracoscopy was performed via the free upper side.

All thoroscopic examinations were performed under a surgical plane of anesthesia.

The animals were premedicated with fentanyl (0.005-0.01 mg/kg, IV) and droperidol (0.25 - 0.5 mg/kg, IV). Anesthesia was induced with propofol (4-6 mg/kg, IV) and maintained on isoflurane vaporized in 100% oxygen using a conventional tracheotube. Lactated Ringer's solution (10 ml/kg/h) was administered intravenously throughout the procedure. Heart rate and blood oxygenation were monitored by pulse-oximetry and CO₂ET by capnography. A catheter was inserted into the femoral artery for analysis of Pa O₂ and Pa CO₂.

The skin was clipped over the entire upper thoracic wall. After aseptic preparation the surgical site was draped and a 1 cm long dorsoventral skin incision was made in the dorsal third of the 8th intercostal space. The skin incision was continued through the intercostal muscles. A 10-mm cannula was advanced through the incision into the thoracic cavity. To establish a pneumothorax and to collapse the lung lobes in the associated hemithorax, a high-flow, pressure-limited insufflating device was connected to the cannula and carbondioxide was insufflated (4 l / min) until an intrathoracic pressure of 3 mm Hg was achieved. Positive-pressure ventilation (10-15 ml/kg) was given to the other lung.

Subsequently either a 10 mm, 0°-view angle or a 5 mm, 25°-view angle endoscope connected to a 300W xenon light source and video camera was introduced through the cannula. Through a second

cannula placed in the 4th intercostal space a hand-shaped tool was inserted to manipulate the lunglobes.

Thoracoscopic photographs were taken. After completing the examination the lungs were reexpanded by overinsufflation of oxygen under direct visualisation through the endoscope and the instrumentation was removed. Afterwards, the chest wall incisions were closed with one suture (vicryl®) in the superficial fascia and one suture (vicryl®) in the skin. For the next 24 hours post - thoracoscopy the dogs were observed for signs of hemorrhage or hypotension by monitoring mucosal membrane color, capillary refill time, pulse and respiratory rates. No complications were encountered.

RESULTS

The lateral surface of the lungs covered by pulmonary pleura were easily to evaluate. The pulmonary pleura adheres tightly to the surface of the lungs and is normally smooth and shiny. With endoscopic magnification, close-up observation permitted clear visualisation of superficial lung alveoli. On the left side of the thorax both the cranial and caudal lobes of the left lung were observed. The cranial lobe is divided into cranial and caudal parts by a shallow cardiac notch (Fig. 1). On the right side of the thorax the cranial, middle and caudal lobes of the right lung were inspected. The accessory lobe of the right lung lies medially to the caudal lobe and is therefore unapproachable for the endoscope. The interlobar fissures were evaluated by displacement of adjacent pulmonary tissue by the hand-shaped tool.

The costal pleura covering the inner surface of the lateral thoracic wall was inspected. The ribs, sternum, intercostal muscles as well as the intercostal blood vessels and nerves that run caudal to each rib were easily perceptible (Fig 1). The m. longus colli lies craniodorsally in the thorax and ventral to the bodies of the first six thoracic vertebrae (Fig. 2). The sympathetic trunk was visible as a white strand lateral to the vertebral bodies (Fig. 3).

The thoracic surface of the diaphragm is covered by the transparent diaphragmatic pleura and describes active movements which were observable (Fig. 4). The diaphragm is composed of a central tendinous part and a peripheral muscular part. On the border between both parts the phrenic

nerves were noticed, penetrating into the diaphragm (Fig 4). The left phrenic nerve was also perceptible coursing across the pericardiac surface (Fig. 5). The right phrenic nerve was visible in the cranial mediastinum lateral to the cranial vena cava, and caudal to the heart in the plica venae cavae (Fig. 6,7).

Cardiac movements were seen through the pericardium, which is opaque and sometimes covered by fat. The best way to approach the pericardium is from the left thoracic cavity (Fig. 1). From this side the thoracic part of the descending aorta was also observable ventral to the vertebral bodies (Fig. 3). After displacement of the cranial lobe of the left lung by using a hand-shaped tool, the ascending aorta and the pulmonary trunk became visible (Fig. 5). In between both vessels the ligamentum arteriosum (Botalli) and the left recurrent laryngeal nerve, which is a branch of the vagal nerve, were defined (Fig. 5). The left vagal nerve was observable coursing across the pericardiac surface at the base of the aorta (Fig. 5). The right vagal nerve runs dorsal to the cranial vena cava and crosses the right azygos vein medially (Fig. 8).

In the cranial mediastinum blood vessels and several adjacent structures were located and defined. The esophagus and trachea were endoscopically visible in each hemithorax (Fig. 9).

In the left hemithorax the left subclavian artery and left brachiocephalic vein and their branches were perceptible (Fig. 2). The thoracic duct is located craniodorsal to the heart and, cranial to the 5th thoracic vertebra, on the left lateral surface of the esophagus and (Fig. 9).

On the right side of the thorax the azygos vein and the cranial vena cava were seen in the cranial mediastinum (Fig. 10). The right azygos vein lies upon the lateral surface of some thoracic vertebral bodies. The thoracic duct was defined caudal to the 6th thoracic vertebra between the descending aorta and the azygos vein. After displacing the cranial lobe of the right lung the broncho-esophageal vein that runs into the azygos vein was inspected at the level of the 7th thoracic vertebra (Fig. 10). Caudal to the heart the caudal vena cava was visible in the plica venae cavae of the right hemithorax (Fig. 7).

All intrathoracic structures that are visible endoscopically are listed in table 1.

TABLE 1 : Intrathoracic structures visible endoscopically

DISCUSSION

In human medicine, thoracoscopy has proven its value for diagnosis and management of different thoracic pathologies. Many traditional open procedures have now been replaced by minimally invasive surgical techniques. In humans as well as in animals, postoperative pain, morbidity, mortality, cost and duration of hospitalization associated with thoracoscopy is less than that with thoracotomy^{4,46,48-52}. Smaller incisions result in improved cosmesis and fewer postoperative complications such as wound infection, hypothermia, dehiscence, bleeding, seroma and hernia formation^{37,47,48}. Disadvantages of the new technology are the specialized and expensive equipment and the need for operator experience, which is a major consideration in performing

thoracoscopic operations successfully⁴⁷. Before performing the technique a good knowledge of the thoracic anatomy, the equipment, the operation techniques and the most suitable access route is a prerequisite. The endosurgical procedures can be more time-consuming compared with thoracotomy⁴¹. Although, the speed of thoracoscopic interventions will improve with the experience of the operator³⁷. Other limitations of thoracoscopy are the small size of some of the patients³⁷.

In veterinary medicine the primary indication for thoracoscopy is for the evaluation of intrathoracic pathology when less invasive methods do not provide sufficient information^{4,33}. Evaluating and obtaining tissue from intrathoracic masses, obtaining lung biopsy and evaluating patients with pleural effusion (as the pleural space can be visually inspected and pleural fluid and tissue can be obtained to be evaluated diagnostically) are significant indications.^{4,31,34-36} Staging of neoplastic disease and preoperative evaluation of lesion resectability are other indications⁴.

In dogs therapeutic interventions such as drainage of empyema or spinal abscesses, oesophageal myotomy, hernioplasty, surgical treatment of bronchopleural fistulas, spontaneous pneumothorax and traumatic thoracic injuries are potential indications for the operative thoracoscopy⁴⁷.

The 10 mm, 0°-view angle and 5 mm, 25°-view angle endoscopes used in this study were very adequate evaluating intrathoracic structures. Using two telescopes with different viewing angles decreases the likelihood of missing a lesion which is 'around the corner'⁴.

There is no specific rule that states where the telescope needs to be inserted, however it should be placed so that it and the instruments that may be inserted, are not parallel or close to each other⁴. Endoscopic examination via the 8th intercostal space with the dog in lateral recumbency made it possible to see most intrathoracic structures, although other positions of the endoscope or the animal could result in better imaging certain structures such as the accessory lobe of the right lung, which was not visible in our study. A ventral approach of the endoscope with the dog in dorsal recumbency could solve this problem. Displacement of lung tissue by means of a hand-shaped tool was required for observation of structures such as the ascending aorta, the pulmonary trunk, the ligamentum arteriosum (Botalli) and the recurrent laryngeal nerve.

Complications that are associated with thoracoscopy are pneumothorax, hemorraghe, cutaneous emphysema, subcutaneous hematoma, infections of the skin or pleural cavity^{31,33}. In the dogs used in this study, no post-operative complications were noticed.

Veterinary operative thoracoscopy is still in the developmental stage but the trend toward minimally invasive surgery will certainly escalate in the next years. The images of thoracoscopic anatomy in dogs that are discussed in this study may be a guide for the operator in performing thoracoscopic surgery.

Ghent University, Salisburylaan 133, 9820 Merelbeke, Belgium

INTRODUCTION

Recommendations regarding treatment and prognosis should be based on the most accurate morphologic and etiologic diagnosis obtainable by diagnostic techniques. Clinicians dealing with dogs with thoracic disorders have a variety of diagnostic techniques at their disposal¹. The standard approach should be to start with the less invasive and less risky procedure and proceed to the more complicated, more intrusive evaluation. After a thorough history, physical examination and laboratory studies, x-rays of the thorax must be performed. Depending on the findings, other techniques such as **computed tomography**, magnetic resonance imaging, ultrasonography, angiography or scintigraphy may follow^{2,3}.

When these procedures have failed to delineate the problem or the therapeutic course, an invasive approach must follow. Thoracocentesis or a pleural biopsy may be performed in cases of pleural disease or intrapleural fluid. Bronchoscopic examination followed by bronchial or pulmonary lavage or biopsy could be indicated in dogs with intrapulmonary or endobronchial disease processes. Depending on the findings, an extrapulmonary CT-guided or a pulmonary fluoroscopic needle biopsy could be accomplished^{3,4}.

If the above approaches reveal mediastinal, pleural, pulmonary or hilar masses, pericardial fluid or pleural fluid that can not be completely removed, a more invasive endothoracic procedure is indicated. Either **thoracoscopy** or open thoracotomy can be used for diagnosis of intrathoracic disorders. Both techniques make the direct visualisation of the lesion possible, while biopsies can be taken and samples for bacterial and fungal cultures can be obtained. The thoracoscopic approach is far less invasive than thoracotomy and leads to a much lower morbidity and mortality^{3,5}. In some cases, evaluation and diagnosis can be followed by minimally invasive thoracic surgery performed by means of thoracoscopy.

RESULTS

Table 1 lists the intrathoracic structures that are visible by each technique. The results are based on former investigations (*see chapter 2.1.1 and 2.1.2*).

TABLE 1 : Intrathoracic structures visible by thoracoscopy and by computed tomography

(^l = only visible in the left hemithorax, ^r = only visible in the right hemithorax, ^{lw} = only visible on lung window setting)

Intrathoracic structures that were not visible on CT-images but were easily observed by thoracoscopy include the parietal and visceral pleura, pericardium, heartbase with ligamentum arteriosum (Botalli), thoracic duct, plica venae cava and several intrathoracic nerves (*see table 1*). On the other hand, visualization of the spinal cord, mediastinum and several vessels was difficult or impossible by thoracoscopy, but easy by CT examination. The lymphnodes could only be seen by computed tomography.

The aspect of the several lung lobes (except for the accessory lung lobe) could be inspected by thoracoscopy, while the inner details were visible on the CT images at lung window setting. The several parts of the heart could not be observed during thoracoscopy due to the surrounding pericardium and were impossible to identify on the CT images as a result of motion artifacts.

CONCLUSIONS

Thoracoscopy as well as CT examination reveal most of the intrathoracic anatomical information and can be used for diagnosing thoracic pathologies. The choice will mainly depend on the clinical history of the animal and the results of former investigations. The fact that thoracoscopy has therapeutic possibilities will also influence the final choice of diagnostic technique.

3.1. The Elbow

The next two chapters concern the investigation of the elbow joint of the clinically normal dog. In the first chapter (chapter 3.1.1) the computed tomographic examination of the elbow is described. The second chapter (chapter 3.1.2) briefly handles the magnetic resonance of this joint and gives a comparison between the results of the 2 techniques, CT and MR. .

However, all figures (anatomic, CT and MR sections) of the elbow joint are combined in figure 2 of the first chapter (chapter 3.1.1) to make a visual comparison easier and simple.

3.1.1. Computed tomography of the elbow joint in clinically normal dogs

SUMMARY

Objective-To use computed tomography (CT) to provide a detailed description of elbow joint structures in clinically normal dogs

Animals- 6 clinically normal adult mixed-breed dogs weighing 24 to 37 kg and one 12-month-old Labrador Retriever weighing 27 kg.

Procedure -To perform computed tomography of both elbow regions, dogs were anesthetized and placed in lateral recumbency. One- and 2-mm contiguous slices were obtained by use of a third generation computed tomographic scanner. Good resolution and anatomical detail were acquired from the computed tomographic images by use of a bone (window width = 3500 Hounsfield units; window level = 500 Hounsfield units) and soft tissue setting (window width = 400 Hounsfield units; window level = 66 Hounsfield units). After euthanasia, the forelimbs from the Labrador Retriever were removed and frozen in water at -18°C . Elbow joints were sectioned into approximately 1-mm thick slab sections by use of an electric planer. Anatomic sections were photographed and compared with the corresponding CT images. Computed tomographic reconstructions of the elbow joint were created in sagittal and dorsal planes.

Results- Structures on the computed tomographic images were matched with structures in the corresponding anatomic sections. The entire humero-radioulnar joint surface could be evaluated on the reconstructed images in the sagittal and dorsal plane.

Conclusions and clinical Relevance- Computed tomographic images provide full anatomic detail of the bony structures of the elbow joint in dogs. Muscles, large blood vessels and nerves can also be evaluated. These results could be used as a basis for evaluation of computed tomographic images of the forelimbs of dogs with elbow joint injuries.

INTRODUCTION

The elbow joint in dogs is a complex and compound joint with multiple articulations : the humeroradial joint, the humeroulnar joint and the proximal radioulnar joint. Though its radiographic anatomy and gross anatomical appearance have been investigated in detail,¹⁻³ the information acquired has limitations, primarily as a result of superimposition of the radial head over the medial coronoid process and the tight fit between the humerus and the trochlear notch of the ulna. Therefore the radiographic diagnosis of elbow lesions including medial coronoid process fragmentation and joint incongruity, can be challenging, and an exploratory arthrotomy has been advocated as a reasonable diagnostic option by some authors.^{4,5} Computed tomography (CT) has a high accuracy for the diagnosis of a fragmented coronoid process (FCP) and associated changes, and may be useful when findings on survey radiographs are negative.⁶⁻¹² The advantages of CT over conventional radiography include the following : depiction of detailed cross-sectional anatomy without distraction from superimposed structures, thereby decreasing the complexity of the image, variation in gray scale formats and enhanced contrast resolution and computer reconstruction of multiplanar images.¹¹⁻¹⁵

In human medicine CT is an established diagnostic tool. In humans with osteochondrosis dissecans, intra-articular fragments, complex intra-articular fractures and, subchondral bone sclerosis, CT is useful and expedient for precise diagnosis, and it helps to identify subtle subchondral lucencies and the presence of loose bodies.¹³⁻¹⁶ The knowledge of the anatomy of the elbow joint on computer tomographic images is necessary to provide accurate interpretation and to describe abnormalities that may be present. The purpose of the study presented here was to provide a detailed description of the elbow joint in clinically normal dogs, as revealed by CT. The results of this CT study were subsequently compared to the results of a MR investigation of the canine elbow (see chapter 3.1.2).

MATERIALS AND METHODS

Animals- Six healthy mature mixed breed dogs weighing 24 to 37 kg and one 12-month-old Labrador Retriever weighing 27 kg were used for our study. Prior to use in our study, the dogs had

their elbow joints physically and radiographically examined. Three radiographic views were obtained: the neutral and flexed mediolateral view and the craniocaudal view. No abnormalities were found on any radiograph.

Computed tomography- Dogs were sedated using fentanyl (0.005 to 0.01 mg/kg, IV) and droperidol ^a (0.25 to 0.5 mg/kg, IV) and then anesthetized with thiopental sodium^b (8 mg/kg, IV). After intubation, anesthesia was maintained with halothane. Dogs were positioned in left lateral recumbency on the computed tomographic scanning table with the elbow joints parallel and extended cranially. The heads of the dogs were pulled back to the lateral side to scan both elbow joints in the gantry. Wedge sponges were placed between both elbow joints to avoid rotation. This position allows a perfect symmetry and comparison of both elbows at the same level. A lateral survey view was made by a third generation CT scanner^c to confirm correct positioning. On a craniocaudal survey view, computed tomographic scans were performed from the top of the olecranon to 3 cm distal to the elbow joint and parallel to the humeroradial joint space.

Two-millimeter thick contiguous views were obtained from the most proximal part of the ulna to 3 cm distal to the radial head. However in the region of the radioulnar joint, 1-mm thick contiguous views were obtained. Individual images were reviewed by use of a bone setting (window width = 3500 Hounsfield units; window level = 500 Hounsfield units) and a soft tissue setting (window width = 400 Hounsfield units; window level = 66 Hounsfield units). Settings for the computed tomographic image technique were as follows : 120 kV and 100 mA. Image acquisition time was approximately 10 minutes. Images from all 7 dogs were formatted on x-ray film^d and evaluated.

Comparison of CT and anatomic images - All 6 dogs recovered from anesthesia. The Labrador Retriever was euthanatized for reasons not associated to orthopedic conditions. The forelimbs of the Labrador Retriever were removed, and frozen at -18 °C with the elbow joints in extension. Subsequently, the frozen elbow joints were removed from the capitulum and trochlea of the humerus down to the proximal portion of radius and ulna. Without thawing, these specimens were embedded in water, stored at -18°C until the surrounding water was frozen, and sectioned into approximately 1-mm thick slab sections (parallel to the humeroradial joint space) by use of an electric planer.^e All anatomic sections were photographed and matched with a corresponding computed tomographic image (bone setting) on the basis of appearance. From this collection, 10 representative matched pairs of the right elbow joint were selected from proximal to distal regions.

Bony and soft tissues were identified on the anatomic sections by comparing all features with a dissected right elbow region of a large-breed dog that had been euthanatized for reasons unrelated to forelimb lameness. The identified structures were subsequently located on the corresponding computed tomographic images (both bone and soft tissue settings), and afterwards the list of identified structures was evaluated on the computed tomographic images of the 6 other dogs. The nomenclature used for designating all structures was in accordance with official anatomic terms.¹⁷ Computed tomography-based reconstructions of the elbow joint in a sagittal and dorsal plane were made to determine whether an evaluation of the entire joint surface could be performed without superimposition of any bony structures.

RESULTS

The 10 selected levels of the right elbow joint of the Labrador Retriever were determined on a craniocaudal computed tomographic survey view (Fig 1). A comparison was made between the computed tomographic images (bone and soft tissue-settings) and the cut-surface of the corresponding anatomic sections of the right elbow joint (Fig 2).

Figure 1– Craniocaudal survey view of the elbow joint of a clinically normal dog indicating the levels (A through J) at which computed tomographic images were obtained.

On the proximal anatomic sections (Fig 2, rows A through F) several osseous, muscular, tendinous, vascular and nervous structures could be identified. Bony structures included the distal portion of the humerus with the lateral and medial parts of the humeral condyle, the lateral and medial

epicondyle, the radial, olecranon and supratrochlear fossa, and the proximal part of the ulna with the olecranon and olecranon tuber, the anconeal process, and the trochlear notch. A number of soft tissue structures, including 9 muscles, were visible on the proximal anatomic sections. Four major blood vessels (3 veins and 1 artery) and 3 nerves could be identified on all sections. The olecranon ligament (row C), the lateral and medial collateral ligaments and the elbow joint capsule were also identified (rows E and F). On the soft-tissue setting, computed tomographic images all of these structures and 1 supplementary muscle, namely the cleidobrachialis muscle were visible. Only the olecranon ligament could not be detected. All previously mentioned bony structures could be identified at the bone setting (rows A through F).

Bony structures that were visible on the more distal anatomic sections (Fig 2, rows G through J) included the proximal portions of the radius and ulna with the lateral and medial coronoid processes, the radial notch and the ulnar tuberosity. Compared with the more proximal located anatomic sections, the tendons of the triceps brachii muscle were absent, the brachialis muscle and biceps brachii muscle were disappearing and five additional muscles could be identified. The distal anatomic sections of the elbow joint (Fig 2, rows H through J) revealed the median vein, formed by the anastomosis of the brachial vein and the median cubital vein, and the median artery which is the continuation of the brachial artery. In addition the anular ligament of the radius (row H) and the antebrachial interosseous membrane (row J) were visible. On the computed tomographic images at the soft tissue setting, the same osseous and soft tissue structures could also be identified, except for the anular ligament of the radius and the antebrachial interosseous membrane. All bony structures that were seen on the anatomic sections were visible on the computed tomographic images at the bone setting.

Sagittal and dorsal reconstructions were made of the right elbow joint of the Labrador Retriever (Fig 3). The sagittal images were reconstructed in the lateral compartment of the joint and through the central ridge of the trochlear notch. All images allowed a thorough evaluation of the shape of the trochlear notch and the congruity of the 3 joint spaces.

For the other 6 dogs, all osseous structures mentioned for the Labrador Retriever could be seen on the computed tomographic images at the bone setting. Similarly, all bony, muscular, nervous and vascular structures that could be identified on the computed tomographic images at the soft-tissue

Figure 2 – Transverse anatomic sections (top left), computed tomographic images (bone image, top right ; soft-tissue image, bottom left) and T1-weighted MR images (TR = 500msec, TE= 12msec; bottom right) of a right elbow joint of a clinically normal Labrador Retriever. setting for the Labrador Retriever were also noticed on the computed tomographic images at the soft-tissue setting for the 6 mixed-breed dogs. In 2 dogs, however, the median artery could not be identified.

DISCUSSION

Lameness referable to the elbow joint is a common finding among young, rapidly growing large- to giant-breed dogs. It can be caused by several developmental conditions including FCP, osteochondritis dissecans (OCD) of the medial part of the humeral condyle, ununited anconeal process, articular anomaly, or joint incongruity.^{5,18-22} Of these developmental conditions, FCP is most common.^{5,20,22-24} They all lead to secondary degenerative joint disease (DJD), loss of range of motion and possible lameness as the animal ages.^{21,22,25-27}

It has been stressed that early diagnosis is essential for the successful treatment of FCP and OCD.^{5,21,23,25-31} Besides the clinical signs, the diagnosis is mostly made on the basis of the radiographic examination of the patients. Unfortunately, the radiographic findings may not be conclusive, and in most instances, the lesions can only be indirectly diagnosed by the appearance of secondary osteophytes. These osteophytes are signs of a secondary DJD and they do not appear until the dog is about seven to eight months old.^{5,12,21,25-29} The ideal situation, however, would be that FCP, OCD, or both within the elbow joint could be directly diagnosed before the radiographic appearance of DJD changes, which are signs of joint damage. Moreover, in some dogs with radiographic changes suggestive of FCP, grossly normal appearing joints can be found at surgery, and in those cases unnecessary arthrotomies are performed.^{4,32,33}

For these reasons, imaging techniques that provide a direct observation of the medial coronoid process and other joint structures would greatly improve the accuracy of preoperative diagnosis of FCP and would contribute to the early diagnosis of this condition. Magnetic resonance imaging has been described as being useful in the detection of FCP, especially in instances of nonmineralised cartilaginous fragments that cannot be seen on computed tomographic images.³⁴ Although arthroscopic techniques to evaluate elbow structures of clinically normal dogs are described³⁵ and the possible arthroscopic changes are reported³⁶, this technique is more invasive than CT and can only evaluate the surface of the lesions.

Although some information on computed tomographic images of the elbow joint in dogs exists³⁷ and a number of reports have been published on the clinical application of CT in elbow disorders^{6,8,33,38} a detailed description of the computed tomographic anatomy of that region in clinically normal dogs is lacking. With the increasing availability of CT for the veterinary profession^{7,11} its application in elbow disease will undoubtedly increase and such a description is useful to detect and evaluate pathologic changes.

In the published reports on CT of the elbow joints in dogs^{6,8,11,14,16,33,38} no definite protocol has been described on the positioning of the dog. We had excellent results with the positioning in lateral recumbency with the elbow joints parallel and extended cranially. The head of the dog was pulled back to the lateral side in order to scan only both elbow joints in the gantry. This positioning allowed us to scan both elbows in perfect symmetry at the same time and made comparison of both joints at the same level possible. Avoiding supplementary tissue within the gantry increases the quality of the images because beam-hardening can be avoided.³⁹

The results of our study indicate that by use of CT not only bony structures can be evaluated but that with the correct window settings a detailed observation of muscular, tendinous, vascular, and even some nervous structures is possible. By studying the axial computed tomographic images, the complexity of the radiographic images can be reduced, although some familiarization with this type of imaging is necessary. Use of CT offers the advantage of evaluating the medial coronoid process and the medial part of the humeral condyle in detail and without superimposition of bony structures. From reports on the arthroscopic findings in FCP³⁶ it is obvious that besides fragmentation of the medial coronoid process there are other pathologic entities in that area including chondromalacia. Fragmentation of the coronoid process is easy to recognise on computed tomographic images but the computed tomographic appearance of other conditions is yet unknown. The exact and objective evaluation of the area of the medial coronoid process requires the study of grossly normal structures to compare with pathologic conditions.

From studying the sagittal and dorsal reconstructions, the entire humero-ulnar joint surface could be studied, as well as the intimate relation of the 3 bony structures (ie, humerus, ulna, and radius) composing the complex elbow joint. In the evaluation of incongruity, the information gained by CT could be more objective than findings obtained by radiography of which the evaluation is always somewhat subjective also as a result of superimposition. Major incongruity is easy to evaluate radiographically but minor incongruity can be hard to recognise. The situation becomes even more complicated as some degree of incongruity has been proven to be normal in humans⁴⁰ and animals.¹ For the detection of minor incongruity comparative studies on clinically normal dogs are also prerequisite.

The major disadvantage of CT is the requirement of general anaesthesia and the purchase and maintenance costs of the equipment. The overall examination time of 10 minutes, however, is acceptable especially if the computed tomographic examination can be combined with the eventual arthroscopic or surgical procedure.

3.1.2. Magnetic Resonance Imaging of the Elbow Joint of the Normal Dog.

Lieve M. De Rycke, DVM

Department of Medical Imaging, Faculty of Veterinary Medicine,
Ghent University, Salisburylaan 133, 9820 Merelbeke, Belgium

SUMMARY

Objective- To use magnetic resonance imaging (MR) to provide a detailed description of elbow joint structures in clinically normal dogs

Animals- 1 clinically normal 12-month-old Labrador Retriever weighing 27 kg.

Procedure- Immediately after the CT examination of the elbow joints (*see chapter 3.1.1*) and under the same anesthesia, MR of the elbow joints was performed in the Labrador Retriever. A commercially available MR equipment^a was used. The animal was kept in the same position as used on the CT scanning table (lateral recumbency with the elbow joints parallel and extended cranially and the head pulled back to the lateral side). Transverse T1-weighted images (TR = 500msec, TE = 12msec) were obtained with a slice thickness of 3 mm from the top of the olecranon to 3 cm distal to the elbow joint and parallel to the humeroradial joint space. After euthanasia, anatomic sections of the elbow were made as described in chapter 3.1.1 and compared with the corresponding MR images. Subsequently the MR images were compared to the corresponding CT images (*chapter 3.1.1*).

Results- All bony structures that were visible on the anatomic sections could be identified on the MR images. From the soft tissue structures visible on the anatomic and CT soft tissue sections, only the median artery and nerve and the radial nerve could not be located on the MR images. On the other hand the anular ligament and of the radius and the olecranon ligament were very distinct on the MR images and unidentifiable on the CT images. In general, vessels and soft tissue structures such as muscles and ligaments were more clearly visible on the MR-images compared to the CT images.

Conclusions and clinical Relevance- MR images provide anatomic detail of bony and soft tissue structures of the elbow joint in dogs. These results could be used as a basis for evaluation of MR images of the forelimbs of dogs with elbow joint injuries and developmental or degenerative conditions, especially nonmineralized cartilaginous MCP.

INTRODUCTION

Magnetic resonance imaging (MR) has been proved to be very useful in humans to examine synovial joints, most notably the knee¹⁻⁴. Although computed tomography (CT) is superior for cortical bone imaging, advantages of MR for the musculoskeletal system include : absence of ionising radiation, direct multiplanar imaging, and an imaging signal directly from the bone marrow, subchondral bone and cartilage⁵. MR has high soft tissue contrast resolution that provides visualization of ligaments, the joint capsule, menisci, and synovial fluid⁶⁻¹¹.

In recent years, MR has been used to a limited extent to diagnose orthopedic conditions in small animals.¹²⁻¹⁴. In a number of reports, investigators have documented the use of IV contrast injection and MR arthrography in diagnosing cartilage abnormalities in canine joints¹⁵⁻¹⁷.

MR and CT have both proved to be quite useful in the diagnosis of canine elbow disorders. CT provides a detailed assessment of the medial coronoid process (MCP), radial incisure, anconeal process and trochlear notch of the ulna, the humeral condyle, elbow joint congruity and osteoarthritis¹⁸. MR readily differentiates the various conditions associated with canine elbow dysplasia, and appears to be superior to CT for identifying nonmineralized cartilaginous MCP.

Improved visualization of other cartilage abnormalities such as humeral condylar osteochondrosis /osteochondritis dissecans (OC/OCD) or wear lesions will likely occur as MR imaging sequences for the elbow are continually refined¹⁸.

A complete MR examination of the elbow joint should include sagittal, dorsal, and transverse plane images to encompass the entire joint¹⁸. In order to make an accurate interpretation of these images a thorough knowledge of the anatomy of the elbow joint on MR images is necessary. The purpose of this chapter was to provide a description of the elbow joint in clinically normal dogs, as revealed by MR and to make a comparison between the results of the CT study (*see chapter 3.1.1*) and this MR study of the canine elbow.

MATERIAL AND METHODS

Immediately after the CT examination of the elbow joints (*see chapter 3.1.1*) and under the same anesthesia, MR of the elbow joints was performed in the Labrador Retriever used in the previous study. A commercially available MR equipment^a was used. The animal was kept in the same

position as used on the CT scanning table (lateral recumbency with the elbow joints parallel and extended cranially and the head pulled back to the lateral side). Transverse T1-weighted images (TR = 500msec, TE = 12msec) were obtained with a slice thickness of 3 mm from the top of the olecranon to 3 cm distal to the elbow joint and parallel to the humeroradial joint space. T1-weighted images were preferred for the good anatomical resolution. Acquisition matrix was 256 x 256.

The anatomical sections of the elbow joints of the Labrador Retriever (*see chapter 3.1.1*) were compared to the corresponding transverse MR images.

From the collection of matched MR and anatomical images, 6 representative pairs were selected from the proximal to distal regions of the elbow (Figure 2 chapter 3.1.1). The identified structures on the anatomical sections (*see chapter 3.1.1*) were subsequently located on the corresponding MR images. Subsequently the MR images were compared to the corresponding CT images (Fig. 2 chapter 3.1.1).

RESULTS

All bony structures that were visible on the anatomic sections could be identified on the MR images. From the soft tissue structures visible on the anatomic sections, only the median artery and nerve and the radial nerve could not be located on the MR images.

All structures identified on the soft tissue setting CT images could be identified on the MR images, except for the median artery and nerve and the radial nerve. On the other hand the anular ligament and of the radius and the olecranon ligament were very distinct on the MR images and unidentifiable on the CT images. In general, vessels and soft tissue structures such as muscles and ligaments were more clearly visible on the MR-images compared to the CT images.

These results are also listed in Table 1

TABLE 1 : Structures of the canine elbow visible on CT and MR scans. (n= not present in the selected views)

CONCLUSION

MR images provide anatomic detail of bony and soft tissue structures of the elbow joint in dogs. Muscles, ligaments, large blood vessels and some nerves are very distinct and can easily be evaluated. On the T1-weighted images, the cortical bone is presented by a band of signal void, ligaments and tendons image with a low signal intensity, whereas adjacent muscle or hyaline articular cartilage demonstrates an intermediate signal intensity. Yellow or fatty marrow generates increased signal intensity.

The choice between CT or MR for elbow pathologies will depend on the suspected lesion. CT is superior for cortical bone imaging, while MR provides a better visualization of ligaments, joint capsule, synovial fluid and cartilage abnormalities. MR appears to be superior for identifying nonmineralized cartilaginous MCP.

These results could be used as a basis for evaluation of MR images of the forelimbs of dogs with elbow joint injuries and developmental or degenerative conditions, especially nonmineralized cartilaginous MCP.

3.2. The Tarsus

The next two chapters concern the investigation of the tarsal joint of the clinically normal dog. In the first chapter (chapter 3.2.1) the computed tomographic examination of the tarsus is described. The second chapter (chapter 3.2.2) briefly handles the magnetic resonance of this joint and gives a comparison between the results of the 2 techniques, CT and MR. .

However, all figures (anatomic, CT and MR sections) of the tarsal joint are combined in figure 2 of the first chapter (chapter 3.2.1) to make a visual comparison easier and simple.

3.2.1. Computed tomography of the tarsal joint in clinically normal dogs

SUMMARY

Objective—To use computed tomography to provide a detailed description of tarsal joint structures in clinically normal dogs.

Animals—6 clinically normal adult mixed-breed dogs weighing 25 to 35 kg and one 12-month-old Bullmastiff weighing 65 kg.

Procedure—To perform computed tomography (CT) of both tarsal regions, dogs were anesthetized and placed in ventral recumbency. One and 2mm thick contiguous slices were obtained, using a third generation CT scanner. Individual images were reviewed, using bone (window width = 3500 Hounsfield units; window level = 500 Hounsfield units) and soft tissue (window width = 400 Hounsfield units; window level = 66 Hounsfield units) settings. After euthanasia, the hind limbs from the Bullmastiff were removed and frozen at -18°C . Tarsal joints were sectioned into approximately 1-mm thick slab sections using a cryomicrotome. Anatomic sections were photographed and compared with the corresponding CT images. CT reconstructions of the tarsocrural joint were created in sagittal and dorsal planes.

Results—Structures on the CT images were matched with structures in the corresponding anatomic sections. The entire tarsocrural joint surface could be evaluated on the reconstructed images in the sagittal and dorsal planes.

Conclusions and Clinical Relevance—CT images provide full anatomic detail of the bony structures of the tarsal joint in dogs. Tendons and large blood vessels can also be seen. These results can be used as a basis for evaluation of computed tomographic images of dogs with tarsal joint injuries.

INTRODUCTION

The tarsal joint in dogs is a compound and complex joint, and although there is a detailed study¹ on the radiographic anatomy of the tarsocrural joint, radiographic evaluation of this region remains difficult because of superimposition of various bony structures, including the distal portion of the tibia and fibula, talus, calcaneus, tarsal, and metatarsal bones. Therefore, the radiographic diagnosis of tarsal lesions, including tarsocrural osteochondrosis, can be challenging, and arthrotomy has been advocated as a reasonable diagnostic option by some authors.²⁻⁵ Computed tomography (CT) offers several advantages over conventional radiography, including the following: elimination of superimposed structures, thereby decreasing the complexity of the image; variation in gray scale formats, which can enhance observation of specific structures; and reconstruction in multiple anatomic planes.⁶

In humans medicine, CT is indicated in situations where detailed information is needed to make a precise diagnosis or to define a tarsal injury more accurately.⁷⁻⁹ In instances of complex intra-articular fractures, subchondral bone sclerosis, and other subchondral bone lesions such as osteochondrosis of the talus, CT is a useful expedient for the diagnosis and may indicate the exact size and location of the lesion.

To provide accurate interpretation of CT images and to recognize abnormalities that may be found, knowledge of the anatomy of the tarsal joint in clinically normal dogs is a prerequisite. The aim of the study presented here was to provide a detailed description of the tarsal joint in clinically normal dogs, as revealed by use of CT. The results of this CT study were subsequently compared to the results of a MR investigation of the canine tarsus (see chapter 3.2.2).

MATERIALS AND METHODS

Animals- Six healthy adult mixed-breed dogs weighing 25 to 35 kg and one 12-month-old Bullmastiff weighing 65 kg were used for our study. Prior to the study, tarsal joints of each dog were physically and radiographically examined. The following 6 radiographic views were obtained: a fully extended and fully flexed mediolateral, a plantarodorsal, a 30° plantarolateral-

dorsomedial and 30° plantaromedial-dorsolateral and a flexed dorsoplantar skyline view. No abnormalities were found on any radiograph.

Computed tomography- Dogs were sedated using medetomidine hydrochloride^a (40 to 50 µg/kg of body weight, IM), and anesthetized with thiopental sodium^b (8 mg/kg, IV). After intubation, anesthesia was maintained with halothane. Dogs were positioned in ventral recumbency on the CT scanning table with the tarsal joints in extension. This position allows a perfect symmetry and comparison of both tarsi at the same level. Lateral and plantarodorsal survey views were obtained, using a third generation CT scanner^c to confirm correct positioning. On the plantarodorsal survey view, CT scans were performed from the distal portion of the tibia and fibula to the proximally located metatarsal bones and parallel to the tarsocrural joint space.

Two millimeter thick contiguous slices were obtained from the most proximal part of the calcaneus to 1 cm distal to the tarsometatarsal joint. However, in the region of the tarsocrural joint, 1-mm thick contiguous views were obtained. Individual images were reviewed using a bone setting (window width = 3500 Hounsfield units; window level = 500 Hounsfield units) and a soft tissue setting (window width = 400 Hounsfield units; window level = 66 Hounsfield units). Settings for the CT image technique were as follows 120 kVp and 100 mA. Image acquisition time was approximately 10 minutes. Images from all 6 dogs were formatted on x-ray film^d and evaluated.

Comparison of CT and anatomic images- All 6 dogs recovered from anesthesia. The Bullmastiff was euthanatized after CT for reasons unrelated to orthopedic conditions. After euthanasia, the hind limbs of this dog were removed and frozen at -18 C with the tarsal joints in extension. The tarsal joints from the distal portion of the tibia and fibula to the distal portion of the talus and calcaneus were embedded in carboxymethylcellulose and sectioned into approximately 1-mm-thick slab sections, using a large specimen cryomicrotome.^e All anatomic sections were photographed and matched with a corresponding CT image (bone setting) on the basis of appearance. From this collection, 12 representative matched pairs of the right tarsal joint were selected from proximal to distal regions. Bony structures and soft tissues were identified on the anatomic sections by comparing all features with a dissected tarsal joint of a large-breed dog that had been euthanatized for reasons unrelated to orthopedic conditions. The identified structures were subsequently located on the corresponding CT images (both bone and soft tissue settings) and afterwards, the list of identified structures was evaluated on the CT images of the 6 other dogs. The nomenclature used

for designating all structures was in accordance with official anatomic terms.¹⁰ Using data from the transverse slices, images can be produced in other planes using computer reformatting. Computed tomography-based reconstructions of the tarsocrural joint in a sagittal and dorsal plane were made to determine whether an evaluation of the entire joint surface could be performed without superimposition of any bony structures.

RESULTS

The plantarodorsal survey view of the 17 selected levels of the right tarsal joint of the Bullmastiff was obtained (Fig 1). CT images (bone and soft tissue settings) and the cut surface of the corresponding anatomic sections of the right tarsal joint of the Bullmastiff were compared (Fig 2 and 3).

**Figure 1 -
Plantarodorsal
survey view of the
tarsal joint of a
clinically normal dog
indicating the levels
(A through Q) at
which computed
tomographic (CT)
images were
obtained**

Most of the bony, tendinous, and vascular structures were visible on the proximally located anatomic sections (Fig. 2, rows A through E). Osseous structures included the distal portion of the

tibia and fibula with the pertaining malleoli, the talus and trochlea tali ridges, and the tuber calcanei. Additionally, tendons of 7 muscles could be identified on the anatomic sections. Five major blood vessels (4 veins and 1 artery) were readily visible on all sections. All of these structures were also visible on the soft tissue-setting CT images except for the rami caudales of the vena saphena lateralis and vena saphena medialis. On the bone setting CT images, only the previously mentioned bony structures could be identified.

On the distally located anatomic sections (Fig 2, rows F through L), bony structures that could be identified included the distal portion of the tibia and fibula with the pertaining malleoli, the talus and calcaneus with a prominent sustentaculum tali, or the collum tali and calcaneus. Soft-tissue structures were almost identical to those described for the proximally located anatomic sections, except that the tendons of the peroneus longus muscle and extensor digitorum lateralis muscle crossed over and, therefore changed positions, the talocalcaneous interosseous ligament was visible, and the extensor digitorum brevis muscle was observed. Distally, the dorsal region of anatomic sections of the tarsal joint contained only a single superficial vein, formed by the fusion of the rami craniales of the saphena lateralis vein and the saphena medialis vein. Except for the extensor digitorum brevis muscle, these osseous and soft-tissue structures were also visible on the soft-tissue setting CT images. In contrast with the more proximal anatomic sections, the rami caudales of the saphena lateralis and saphena medialis veins could be located. On the bone-setting CT images, all bony structures seen on the anatomic sections could be identified.

Analysis of CT images made at the most distal levels (Fig 3) revealed the talus, calcaneus, and os tarsi centrale; the os tarsi centrale and os tarsale quartum; the os tarsale secundum, tertium, and quartum; the os tarsale primum, secundum, tertium, and quartum; or metatarsals II, III, IV, and V.

Sagittal and dorsal reconstructions were made of the right tarsocrural joint of the Bullmastiff (Fig 4). The sagittal images allowed a thorough evaluation of the lateral and medial parts of the tarsocrural joint including the lateral and medial ridge. On the dorsal reconstructions, the tarsocrural joint could be evaluated from the dorsal to plantar surface in detail.

For the other 6 dogs, all osseous structures mentioned for the Bullmastiff could be seen on the bone-setting CT images. Similarly, all bony, tendinous, and vascular structures that could be identified on the soft tissue-setting CT images of the Bullmastiff were also noticed on the soft-tissue setting CT images of the 6 mixed-breed dogs. Additionally, in 4 dogs, the rami craniales of the saphena

lateralis and saphena medialis veins were distinct, and in 1 of these dogs, the rami caudales of both veins were also visible. In another dog, however, the tendons of the peroneus longus and extensor digitorum longus muscles could not be identified.

DISCUSSION

Although some information on CT of the tarsal joint in dogs exists,¹¹ a detailed description of imaging in clinically normal dogs is lacking. The results of our study indicate that not only is a detailed evaluation of the bony structures of the tarsal joint in dogs possible but that, by adjusting the window and making use of the varying gray scale formats, many soft tissues, including tendons and vascular structures, can be viewed as well. The complexity of the radiographic image caused by superimposition of bony structures can be overcome by studying the axial CT images of the tarsal joint, although some familiarization with this type of imaging is necessary. By studying the sagittal and dorsal reconstructions, the entire tarsocrural joint surface (ie, the lateral and medial tarsal ridge and also the dorsal and plantar surfaces) can be evaluated. These results suggest that CT could be of use in the diagnosis of tarsocrural osteochondrosis, especially when the lateral ridge is involved and superimposition of the calcaneus over the lateral tarsocrural compartment hinders fragment detection. Moreover, CT could be of use in determining the therapeutic strategy for tarsocrural osteochondrosis.

Using CT, the exact localization, size, and number of fragments may be determined in dogs with tarsocrural osteochondrosis. The location of the fragments on the trochlear ridge, especially on the lateral part, can be diverse, but this information is useful for the orthopedic surgeon who wants to use a minimal exposure technique to remove the fragments.^{1,12} A disruption of the collateral ligament complex following an arthrotomy could create postsurgical instability and, thus, may compromise the long-term prognosis of affected dogs following surgical treatment.¹³ For arthroscopic treatment of these lesions, exact location is prerequisite knowledge, because various arthroscopic approaches must be performed depending on the location of the fragments. The number and size of the fragments is also important information for determining whether fragments should be removed or repaired. Osteoarthritic changes may progress because of instability or incongruity of the joint following removal of a large fragment.¹⁴ Several authors^{2,13,15,16} claim that the reattachment of osteochondrosis fragments would be preferable to removal, especially when the lateral talar ridge is involved and traumatic fragmentation with avulsion of the short collateral ligaments has been identified.

Computed tomography could also be of use in instances of complex tarsal fractures where the same problem of superimposition of the surrounding bony structures exists and could provide information

contributing to adequate treatment. Another application for CT of the tarsal joint is for detection of subchondral sclerosis, which can be done by measuring the difference in density between cortical and spongy bone. In instances of sclerosis, the density of the spongy bone is increased. Changes in cortical thickness can also be measured.

Computed tomography is becoming more readily available to veterinarians than in the past and is becoming more commonly used for the diagnosis of orthopaedic disorders in small animals.^{17,18} Major disadvantages of the technique include cost and the need for general anesthesia. The examination time is, with the type of scanner used in our study, about 10 minutes, which is acceptable. Obtaining 6 radiographic views of the tarsal joint is more time consuming, and in some countries, general anesthesia is obligatory for radiation safety reasons.¹ If access to additional software for multiplanar reconstruction is not available, evaluation is limited to the axial images. This requires more time to evaluate the true extent of possible lesions. Still, the information gained from only the transverse images is worthwhile.

3.2.2. Magnetic resonance imaging of the tarsal joint of the normal dog.

Lieve M. De Rycke, DVM

Department of Medical Imaging, Faculty of Veterinary Medicine,
Ghent University, Salisburylaan 133, 9820 Merelbeke, Belgium

SUMMARY

Objective—To use magnetic resonance imaging (MR) to provide a detailed description of tarsal joint structures in clinically normal dogs.

Animals—1 clinically normal 12-month-old Bullmastiff weighing 65 kg

Procedure— Immediately after the CT examination of the tarsal joints (*see chapter 3.2.1*) and under the same anesthesia, MR of the tarsal joints was performed in the Bullmastiff using a 1.5 Tesla closed MR equipment^a. The animal was kept in the same position as used on the CT scanning table (ventral recumbency with the tarsal joints in extension). A series of transverse combined T2 - proton density images (TR = 3500msec, TE = 84msec) were obtained with a slice thickness of 3mm from the distal portion of the tibia and fibula to the proximally located metatarsal bones and parallel to the tarsocrural joint space. After euthanasia, anatomic sections of the tarsus were performed as described in chapter 3.2.1 and compared with the corresponding MR images. Afterwards a comparison with the corresponding CT images was made (chapter 3.2.1).

Results— All bony and soft tissue structures that were visible on the anatomic sections could be identified on the MR images.

All structures identified on the soft tissue setting CT images could be identified on the MR images. In addition the talocalcaneal interosseous ligament and the extensor digitorum brevis muscle could be located on the MR images. In general, most blood vessels and tendons were much more clearly visible on the MR images compared to the CT images.

Conclusions and Clinical Relevance— MR images provide anatomic detail of bony and soft tissue structures of the tarsal joint in dogs.

These results could be used as a basis for evaluation of MR images of dogs with tarsal joint injuries.

INTRODUCTION

Magnetic resonance imaging (MR) is used routinely for the diagnosis of injuries of the musculoskeletal system in humans because of its superb soft tissue contrast¹. The image resolution of ligaments, tendons, articular cartilage, subchondral bone and other soft-tissue structures surrounding joints, along with the ability to image in multiple planes has made MR the preferred imaging modality for diagnosis of traumatic, degenerative and inflammatory diseases of joints in humans².

Although few veterinarians currently have the equipment available, MR as a major diagnostic tool in veterinary medicine is increasing. Several studies have investigated MR of the orthopedic system of the horse and the dog. MR of the normal equine carpus, stifle, tarsus and foot has been described³⁻⁹. Furthermore, MR of normal and pathologic models of the canine shoulder, carpal and stifle joints has been published¹⁰⁻¹⁷. However, similar studies of the canine tarsal joint have not been reported. The purpose of this chapter was to describe the normal MR anatomy of the canine hock and to make a comparison with the corresponding CT images.

MATERIAL AND METHODS

Immediately after the CT examination of the tarsal joints (*see chapter 3.2.1*) and under the same anesthesia, MR of the tarsal joints was performed in the Bullmastiff using a 1.5 Tesla closed MR equipment^a. The animal was kept in the same position as used on the CT scanning table (ventral recumbency with the tarsal joints in extension). A series of transverse combined T2 -proton density images (TR = 3500msec, TE = 84msec) were obtained with a slice thickness of 3mm from the distal portion of the tibia and fibula to the proximally located metatarsal bones and parallel to the tarsocrural joint space.

The anatomical sections of the tarsal joints of the Bullmastiff (*see chapter 3.2.1*) were compared to the corresponding transverse MR images. The structures identified on the anatomical sections (*see chapter 3.2.1*) were subsequently located on the corresponding MR images.

From the collection of matched MR and anatomical images, 10 representative pairs were selected from the proximal to distal regions of the tarsal joint (Figure 2 chapter 3.2.1). Afterwards a comparison with the corresponding CT images was made (Figure 2 chapter 3.2.1).

RESULTS

All bony and soft tissue structures that were visible on the anatomic sections could be identified on the MR images.

All structures identified on the soft tissue setting CT images could be identified on the MR images. In addition the talocalcaneal interosseous ligament and the extensor digitorum brevis muscle could be located on the MR images. In general, most blood vessels and tendons were much more clearly visible on the MR images compared to the CT images.

These results are also listed in Table 1

TABLE 1 : Structures of the canine tarsal joint visible on CT and MR scans. (n= not present in the selected views)

CONCLUSION

MR images provide anatomic detail of bony and soft tissue structures of the tarsal joint in dogs. Muscles, tendons, ligaments, large blood vessels are very distinct and easier to evaluate compared to the CT images. On this proton-density images, the cortical bone generates a low signal. The brighter signal of articular cartilage is not distinguishable from synovial fluid. Yellow and fatty marrow, muscles and tendons demonstrate a low signal intensity.

The choice between CT or MR for diagnosing tarsal pathologies will mainly depend on the kind of suspected lesion. CT provides more detail of the cortical bone, while MR is superior for recognizing abnormalities of the joint capsule, ligaments, cartilage and subchondral bone.

These results could be used as a basis for evaluation of MR images of dogs with tarsal joint injuries.

A thorough knowledge of the normal cross-sectional anatomy of the body is most essential for interpretation of CT and MR, as the radiologist is confronted with detailed anatomical cross-sections instead of two-dimensional “shadow pictures” seen on radiographs. These new developments have caused difficulties when evaluating CT and MR images, because the knowledge of the normal conventional anatomy and radiographic anatomy was not longer sufficient for recognising structural abnormalities in diseased animals.

Since CT and MR have become more available to veterinarians, several articles devoted to the cross-sectional normal anatomy of specific body regions have been published¹⁻⁴. The idea for comparing normal cross-sectional anatomy to normal CT or MR images is not original⁵⁻¹⁴. These articles and books have been most helpful in performing this work, however they have not alleviated the prevailing great need for more detailed investigations on the normal cross-sectional anatomy as seen on CT and MR images. Based on the perception that a color atlas comparing the normal cross-sectional anatomy to the CT and MR anatomy would be supportive in the interpretation of the increasing numbers of cross-sectional images, several CT and MR images were obtained in transversal planes of clinically important regions of the canine body. Taking advantage of the MR characteristics of depicting soft tissue in great detail and in superior spatial resolution, and combining the MR scans with CT pictures of the same region showing the calcium containing structures, the basis for a unique atlas has been created. The various regions are illustrated using a sufficient number of transverse CT and MR scans and all anatomical structures depicted on the images were labelled in great detail. The regions of the canine body selected for this work were chosen based on their clinical importance, particularly the frequency of pathologies associated with these regions.

Interpretation of the findings on CT and MR images is a prerequisite to establish a precise diagnosis in clinical cases. Besides the use of this atlas, interpretation of CT and MR images can also be simplified by comparing with the opposite side. Furthermore, strictly standardised positioning produces symmetric images, making interpretation much easier. On the transverse images, structures can also be identified by examining adjacent transverse images. The scanned structure can thus be followed as it appears and disappears in relation to recognisable surrounding organs.

The CT images were performed on a third generation CT scanner^a. Dependant on the region, soft tissue window (brain, thorax, elbow, tarsus), bone window (nasal cavities, elbow, tarsus) or lung

window (thorax) settings were used. This CT scanning technique allows a slice thickness of 1 mm resulting in slices with an increased signal/noise ratio¹⁵. Such thin slices are very effective for examination of small lesions and small organs. An increase in mAs can compensate for image noise associated with narrow slice collimation which can be very interfering. Thin slices however require long scan times, which result in high doses of anaesthesia and radiation and increases the cooling time for the thermal tube of this third generation scanner. Thick slices have a large scanning area and low noise but also have a large partial volume effect¹⁵. Slice thicknesses of 2 mm for the brain, 5 mm for the nasal cavities, 5 mm for the thorax, and 2 mm for the joints were used.

Most generators support a wide range of exposure techniques from 80 to 140 kilovolts (kV) and 30 to 500 milliamperes (mA)¹⁶. A high kV is always used to ensure adequate penetration, and for very dense objects to minimise beam hardening. The choice of milliamperes seconds (mAs) depends on the selected kV and slice thickness. High mAs will increase image detail because it reduces image noise, but radiation dose and tube cooling time increases^{15,17}. In our investigations 120 kVp and 130 mAs were used. The chosen scan time was 3 seconds. A longer scan time may result in improved image detail, but may cause motion artefacts (including respiratory motion) and can eventually cause x-ray tube heating¹⁸.

The MR studies were performed using a 1.5 closed Tesla MR unit^b. In general, T1-weighted images provide superior tissue contrast and anatomic detail, while T2-weighted images are more sensitive to demonstrate fluid (e.g. CSF), edema and inflamed tissues which show increased signal intensity. Proton-density images are balanced T1- and T2-images.

For the present study (chapter 1.1.2), T1-weighted images were chosen as they demonstrate very well the over-all morphology of the brain. On the other hand, the difference between the gray and white matter is indistinct and almost similar to CT. T2-weighted images are highly sensitive in detecting pathologic processes affecting the brain parenchyma^{16,19}. Vascular structures show signal void in all regular T1- and T2-weighted and proton-density images. The appearance of vessels can be changed by applying a special technique of magnetic resonance angiography¹⁶.

When evaluating the nasal cavities and paranasal sinuses with MR, the standard protocol includes transverse and dorsal T1- and T2-weighted images¹⁶. In the present study, also proton density images were performed. Cortical bone and air are not well depicted on the MR-images. In contrast, the mucosal covering of the nasal cavities and sinuses is distinct on both T1- and T2-weighted

images due to the intermediate signal intensity. Low viscosity secretions (in case of sinusitis) appear as hypointense on T1-weighted images and hyperintense on T2-weighted images. For mucous secretions with higher viscosity, the signal intensity on T2-weighted images decreases. A fungal sinusitis is characterized by a low signal intensity on T1-weighted images and a signal void on T2-weighted images. This is due to the presence of paramagnetic metals (iron and manganese present in *Aspergillus* colonies)¹⁹. The signal intensity of nasal tumors on MR images is dependent on the nature of the neoplasm¹⁹.

For the examination of the elbow joint, T1-weighted images were chosen for the good anatomical resolution. Proton density images were selected for the tarsus, as T1- and T2-weighted images were not available. For the musculoskeletal system in general, cortical bone generates a low signal on all pulse sequences. Yellow or fatty bone marrow generates increased signal intensity on T1-weighted acquisitions. Signal intensity decreases with progressive T2 weighting^{20,21}. Collagen-containing ligaments and tendons image with low signal intensity, whereas adjacent muscle or hyaline articular cartilage demonstrates an intermediate signal intensity on a T1-weighted image²¹. Cortical bone is presented by a void signal on T1-weighted images²⁰. On T2-weighted sequences the bright signal of the articular cartilage is not distinguishable from synovial fluid²⁰.

For most of the CT and MR images in this work, no intravenous contrast medium was administered, as the aim was to describe plain images made by standard procedures. Only for the CT study of the canine brain, contrast medium was applied, but the post-contrast images were not used as they differed little from the pre-contrast images. For detection of brain pathologies however, the use of contrast medium is routine. Postcontrast CT and MR images enhance the pituitary gland, dural structures such as the falx cerebri and the tentorium cerebelli, arterial structures and the choroid plexuses of the lateral, third, and fourth ventricles^{16,22}.

The CT and MR examinations of the nasal cavities were also performed on plain images, as the use of intravenous contrast medium has not been shown to aid in the recognition of anatomical structures¹⁶. IV contrast medium can be useful in nasal cavities with pathologic changes to enable differentiation between fluid and soft tissue or to define more accurately the nature of an abnormal soft-tissue structure^{23,24}. The use of contrast medium in MR examinations has been proposed as a method for differentiating sinunasal neoplasms from inflammatory masses²⁵.

For the CT images of the thorax, no IV contrast medium was injected. When performing CT of the diseased thorax, an IV bolus of contrast medium is very useful in the diagnosis of intrathoracic

vascular lesions, for defining the extent of mediastinal masses and their relation to structures such as major vessels or the heart, and to enhance the pleura and heart²⁶⁻³⁰.

The CT and MR studies of the elbow and tarsal joints were also made by means of plain images. The indications for CT-arthrography include detecting cartilaginous intrasynovial loose bodies and synovial abnormalities, and assessing the cartilaginous surfaces³¹. The requirement of intraarticular contrast in MR is not necessary as synovial fluid has a bright signal intensity on T2-weighted images and the articular hyaline cartilage can be selectively highlighted on fast scan sequences²¹.

The judicious use of CT and MR requires a working knowledge of the utility and pitfalls of their application in the diagnosis of various disorders in each region of the body.

CT and MR have many applications in detecting brain pathologies. However, each imaging modality has its limitations. The limitations of CT include a poor resolution in changes involving the white matter, artefacts which may significantly degrade the images through the region of the fourth ventricle, and the need for a large amount of intravenous contrast when defining intracranial masses or evaluating the vascular component of the lesions¹⁹. All these factors are obviated with MR. MR allows imaging in all three orthogonal (sagittal, dorsal and transversal) planes. The resolution of the gray and white matter is better than with CT and the vascular anatomy can be evaluated with noninvasive, magnetic resonance angiography (MRA). The limitation of MR is primarily related to the difficulty in recognizing fresh hemorrhage, mineral deposition from flow-related artifacts, and subtle changes involving the osseous structures¹⁹.

MR offers some advantages over CT scans when imaging pathologic conditions of the nasal cavities and paranasal sinuses. In contrast to CT, MR allows not only differentiation between the nasal mucosa and other soft tissues or fluid, but is able to map the extent of a mass or inflammatory process into either the orbit or intracranial cavities¹⁶. For this purpose, the multiplanar capabilities of MR are unsurpassed. In addition, the signal characteristics of a sinonasal mass may help to distinguish inflammatory from neoplastic sinonasal diseases³²⁻³⁴. If the mass is neoplastic, this ability allows for better surgical and radiation planning. In contrast, the bony architecture or destruction will be more clearly visible on the CT images.

CT is particularly effective in evaluating trauma, soft tissue and bony lesions, infection and degenerative disorders of the musculoskeletal system. CT is especially useful in the assessment of small joints that require thin section evaluation. CT provides high bone detail in cross-sectional display. Reformatting capabilities and three-dimensional display of CT are functions that facilitate

the understanding of complex anatomy and spatial relationships. The drawbacks to CT include the use of ionizing radiation and the narrow range of soft tissue contrast. Nonorthogonal imaging capabilities result in a loss of resolution when reformatting cross-sectional images. Routine use of thin-section CT images to increase the resolution of reformatted images is not practical in studies of large anatomic structures²¹. MR allows for direct multiplanar imaging of the appendicular joints in nonorthogonal planes and can differentiate fat, fluid, muscle, tendon, cartilage, neurovascular structures and cortical bone in both normal and pathologic states^{20,21}. The ability to noninvasively image and characterize early changes in bone marrow, subchondral bone, and cartilage provides a more precise evaluation in patients presenting trauma, infection, and neoplasia. MR is limited in that the identification of small soft tissue or joint calcification is inferior to that of CT. For imaging of the bony cortex, cortical edge detail of CT is superior to MR. MR requires more detailed imaging protocols adapted to both anatomy and pathology; often these must be joint specific²¹. Furthermore, MR is limited in that it has a greater sensitivity to motion than CT²¹.

For the study of the thorax, we choose to compare the results of the CT examination with those of thoracoscopy, as MR of the thorax has little applications in veterinary medicine at present. In human medicine, MR has a clear advantage over other imaging modalities when evaluating cardiac and vascular disorders of the thorax, but its role in the evaluation of parenchymal lung disease is limited¹⁶. Obstacles to lung imaging include respiratory motion and magnetic susceptibility effects caused by air-tissue interfaces. For imaging mediastinal abnormalities, MR has also two potential disadvantages compared to CT, namely its low potential to demonstrate calcification and its poor spatial resolution¹⁶. Rapid evolution of MR technology suggests that some of these problems may be overcome in the near future. Assessment of chest wall disease and peridiaphragmatic processes, which do not suffer as much from respiratory or magnetic susceptibility artifacts, already benefits from the multiplanar capabilities of MR and its improved soft tissue contrast¹⁶.

To obtain the anatomic slices described in the present study different techniques have been used. For the fixed brain a stainless-steel knife was sufficient to make 5-mm thick transverse sections. The same knife was used to cut the decalcified and fixed nasal cavities and paranasal sinuses. Because of its much bigger size, the frozen thorax was cut into 10-mm thick slices by use of an electric bandsaw^c. For the anatomic sections of the frozen elbow joint an electric planer^d was

chosen as the cryomicrotome^e technique used to section the frozen tarsus was too time-consuming and not available in our department.

The great need for a clear CT and MR atlas in our department was the motivation for this work. In the future, other regions of the canine body such as the knee, hip, carpal joint and the abdomen will be investigated in a similar way, in order to complete this comparative atlas.

This study presents the cross-sectional anatomy of several clinically important regions of the normal canine body. Labeled gross anatomical sections are used to identify a wide range of structures on corresponding CT and MR images. This detailed comparative description is intended to serve as an atlas for clinicians, allowing an optimal interpretation of CT and MR images of dogs affected with pathologies - except for disorders that transform the normal anatomy of a region severely by their size or invasive growth.

In the first chapter CT and MR images of two regions of the head namely the brain and the nasal cavities including the paranasal sinuses, were examined.

To perform CT and MR of the brain, 4 shepherd dogs were anesthetized and placed in ventral recumbency. For CT, 2-mm thick pre- and post-contrast transversal slices were made, ranging from the cribriform plate of the ethmoid bone to the cranial part of the atlas, using a soft-tissue setting. MR of the brain was performed in one of the dogs that was kept in the same position as used on the CT scanning table. Transverse, 4-mm thick T1-weighted and T2-weighted MR images were obtained from the same regions of the head.

Afterwards, one of the dogs was euthanatized and the brain was prepared, fixed, embedded in gelatine and sectioned into 5-mm-thick transversal slices. The anatomic sections were photographed and numerous structures of the canine brain and the various parts of the ventricular system were identified.

Most of these structures could also be located on the corresponding CT images, by the use of landmarks such as adjacent radiolucent cerebrospinal fluid and bony structures. Unfortunately, it was not possible to distinguish some parts of the telencephalon, such as the internal capsule and hippocampal gyrus, nor some structures of the diencephalon, including the optic tract, epiphysis, infundibulum and the tuber cinereum. From the mesencephalon, the interpeduncular fossa, red nucleus, and the substantia nigra were not identifiable. At the level of the metencephalon the cerebellar white matter, floccular lobe and the middle cerebellar peduncle could not be localized. Some structures of the medulla oblongata including the medial ventral fissure, pyramids and the central canal were impossible to distinguish, and neither were the choroid plexuses of the lateral and fourth ventricles. On the CT images, the bony and soft tissue structures surrounding the brain were additionally labeled.

Most of the brain structures that were visible on the anatomic sections could be identified on the MR images, except for some parts of the diencephalon such as the epiphysis, hypophysis with

infundibulum and the mamillary body, probably because these structures were not present in any of the sections. The mesencephalic red nucleus and substantia nigra could not be located on the MR images and neither was the cerebellar white matter.

When comparing the MR images of the brain with the corresponding CT images, all brain structures and surrounding soft tissue structures could be much better visualized with MR.

Moreover, several brain structures such as the internal capsule, optic tract, hippocampal gyrus, rostral and caudal collicle, interpeduncular fossa, brachium of the pons, median ventral fissure, floccular lobe, pyramid of the medulla oblongata and the choroid plexuses of the fourth and lateral ventricles could be located on the MR images and were unidentifiable on the CT images. Only the bony structures of the skull, and in particular the foramina, fossae, canals and sulci, were more distinct on the CT images compared to the MR images.

These results could be used as a basis for evaluation of CT and MR images of the brain of dogs affected with pathologies.

Two dogs were used to perform CT and MR of the nasal cavities and paranasal sinuses. The first dog was anesthetized and positioned in ventral recumbency for both examinations. For CT, 5-mm thick transversal slices from the caudal part of the frontal sinuses to the nostrils were made using a bone setting. The same dog underwent a MR examination and transversal T1-weighted, T2-weighted and proton density MR sequences were performed. The second dog was positioned in dorsal recumbency with the head perpendicular to the table to obtain dorsal images and the same CT and MR protocols were used.

At the end of the examinations, both dogs were euthanatized and the skulls were, after preparation and decalcification, embedded in gelatine and sectioned into 5-mm thick transversal slices. Each anatomic section was compared with the corresponding CT and MR images, and all recognizable structures were labeled on all images. The various facial bones that form the wall of the nasal cavities as well as most parts of the nasal cavities, such as the nasal conchae, septa, meatuses and all endo- and ectoturbines, could easily be identified on the anatomic sections. The medial and lateral parts of the frontal sinuses and the maxillary recess were also visible. Additionally, several adjacent structures that remained on the skull were labeled.

On the CT scans it was also possible to identify various structures of the nasal cavities and paranasal sinuses, except for the dorsal, middle and ventral nasal meatuses and some of the

ectoturbينات. It was less obvious to distinguish a number of surrounding soft-tissue structures on the CT scans.

On the MR scans, the facial bones could not be identified, but most of these could be located due to their void signal. In contrast, the conchae, conchal septa, and turbinates -except for some of the ectoturbينات- were well imaged because of their distinct mucosal covering. The surrounding soft-tissue structures were clearly visible on MR scans, especially when compared to the CT scans. Considering these results, CT and MR images provide consistent evaluation of all structures of the nasal cavities and paranasal sinuses. In conclusion, both techniques could be useful for evaluation of nasal diseases.

In the second chapter of this study the anatomy of the thorax was described as revealed by CT and by thoracoscopy, followed by a comparison between both techniques.

For CT examination of the thorax, 4 dogs were anesthetized and positioned in ventral recumbency. Transversal CT images from the thoracic inlet to the diaphragm were made with a slice thickness of 5-mm and reviewed by use of soft tissue and lung settings. One dog was euthanatized and frozen, and the thorax was subsequently sectioned at 10-mm thick intervals. For each anatomic slice, a corresponding CT image was searched for, and anatomic structures were matched.

On the anatomic sections, the various intrathoracic parts of the respiratory tract and the different lung lobes were clearly visible. Major blood vessels could also readily be seen in the cranial mediastinum and thoracic cavity. Other intrathoracic structures, such as the heart with its chambers and valves, esophagus, lymph nodes and muscles were easily to distinguish, and so were the various parts of the thoracic wall and the surrounding tissues.

Most of the previously mentioned structures of the thorax could be identified on CT images at the soft tissue setting, except for the different parts of the heart, some vessels, the nuchal ligament, diaphragm, the various lobes of the lungs and the lobar bronchi. On CT images obtained at the lung setting, only the parts of the respiratory tract and some large vessels were distinct. Only contours of the heart and liver only were visible, and the presence of air in the esophagus and in the cardia and fundus of the stomach revealed the position of these organs.

For thoracoscopy, 4 dogs were anesthetized and placed in left or right lateral recumbency. The endoscope was advanced in the thoracic cavity via the free upper side and photographs were taken.

A large number of endoscopically visible intrathoracic structures of the left and right hemithorax were identified.

On both sides, the pulmonary and costal pleura, the diaphragm, the heart surrounded by pericardium and the various parts of the thoracic wall, including nerves and vessels, were easily perceptible. In the cranial mediastinum, the esophagus and trachea could be located in each hemithorax.

In the left hemithorax, the cranial and caudal lobes of the left lung were observed and large blood vessels, such as the ascending and descending aorta and the pulmonary trunk were visible. At the heart base, the ligamentum arteriosum (Botalli) and the left recurrent laryngeal nerve were defined, while the left vagal and phrenic nerves were observable coursing across the pericardiac surface. In the cranial mediastinum the thoracic duct, the left subclavian artery and left brachiocephalic vein and their branches were perceptible.

On the right side of the thorax the cranial, middle, and caudal lobes of the right lung could be evaluated. Caudal to the heart, the caudal vena cava and right phrenic nerve were visible in the plica venae cavae. In the cranial mediastinum, the azygos vein, cranial vena cava, right vagal and phrenic nerves, the broncho-esophageal vein and the thoracic duct were seen.

Afterwards the 2 techniques for examination of the thorax were compared. Intrathoracic structures that were not visible on CT-images but easily observed by thoracoscopy included the parietal and visceral pleura, pericardium, heartbase with ligamentum arteriosum (Botalli), thoracic duct, plica venae cavae and several intrathoracic nerves. On the other hand, visualization of the spinal cord, lymphnodes, mediastinum and several vessels was difficult or impossible by thoracoscopy, but easy when using CT examination.

The surface morphology of the different lung lobes (except for the accessory lung lobe) could be inspected by thoracoscopy, while the inner details were visible on the CT images at lung window setting. The various parts of the heart could not be observed during thoracoscopy due to the surrounding pericardium and were impossible to identify on the CT images as a result of motion artefacts.

In conclusion, thoracoscopy as well as CT examination of the thorax revealed a wide range of the intrathoracic anatomical information and can be used for diagnosing thoracic pathologies. The choice between both techniques will mainly depend on the clinical history of the animal and the results of former investigations. The fact that thoracoscopy has therapeutic possibilities will also influence the final choice of diagnostic technique.

In the third chapter of this work, the CT and MR anatomy of two appendicular regions, i.e., the elbow and tarsus, were described and compared.

To perform CT of the elbow regions, 7 dogs were anesthetized and placed in lateral recumbency. One- and 2-mm thick slices were obtained, ranging from the top of the olecranon to 3 cm distal to the elbow joint, in parallel planes to the humeroradial joint space. Images were reviewed using a bone and soft tissue setting and CT reconstructions of the elbow joint were made in sagittal and dorsal planes. MR of the elbow joints was performed in one of the dogs (a Labrador retriever) that was kept in the same position as on the CT scanning table. Transversal 3-mm thick T1-weighted and T2-weighted images were obtained from the same regions as mentioned above. After the examinations, the Labrador retriever was euthanatized and the forelimbs were removed and frozen. The elbow joints were sectioned into approximately 1-mm thick slab sections, which were photographed and compared with corresponding CT and MR images.

On the anatomic sections several osseous, muscular, tendinous, vascular and nervous structures could be identified. On the CT images at the soft tissue setting, the same osseous and soft tissue structures could be identified, except for the anular ligament of the radius and the antebrachial interosseous membrane. All bony structures that were seen on the anatomic sections were also visible on the CT images at the bone setting and the entire humero-radioulnar joint surface could be evaluated on the reconstructed CT images.

On the MR images, all anatomic structures that were visible on the anatomic sections could be identified, except for the median artery and nerve, and the radial nerve. Subsequently, the MR images were compared to the corresponding CT images at the soft tissue setting and, except for the median artery and nerve and the radial nerve, the same structures were defined. On the other hand, the anular ligament of the radius was very distinct on the MR images and unidentifiable on the CT images.

Most of the anatomic structures of the elbow joint are recognizable on the CT and MR images. Consequently this compilation could be used as an atlas for evaluation of CT and MR images of the forelimbs of dogs with elbow joint injuries and developmental or degenerative conditions.

For CT examination of both tarsal regions, 7 dogs were anesthetized and placed in ventral recumbency. Transverse, 1- and 2-mm slices were obtained from the most proximal part of the calcaneus to 1 cm distal to the tarsometatarsal joint, using bone and soft tissue settings. Afterwards,

CT reconstructions of the tarsocrural joint were created in sagittal and dorsal planes. MR of the tarsal joints was performed in one of the dogs that was kept in the same position as mentioned above. Transverse, T1-weighted and T2-weighted images were obtained with a slice thickness of 3 mm. After euthanasia, the hind limbs of one of the dogs were removed and frozen and the tarsal joints were sectioned into approximately 1-mm thick slices. Anatomic sections were photographed and compared with the corresponding CT and MR images.

Most of the bony, tendinous, and vascular structures were visible on the anatomic sections and all of these structures were also perceptible on the soft tissue setting CT images, except for the extensor digitorum brevis muscle and the talocalcaneal interosseus ligament. On the bone setting CT images, only the previously mentioned bony structures could be identified. The entire tarsocrural joint surface could be evaluated on the reconstructed CT images in the sagittal and dorsal planes. All bony and soft tissue structures visible on the anatomic sections could be identified on the MR images. When comparing the MR images to the corresponding soft tissue CT images, the same structures as well as the talocalcaneal interosseous ligament and the extensor digitorum brevis muscle could be located on the MR images. In general, most blood vessels and tendons were more clearly visible on the MR images compared to the CT images.

This detailed atlas of the tarsal joint formed an excellent anatomical basis for clinicians to evaluate CT and MR images of dogs affected with tarsal joint injuries.

The findings of the present study, together with the results of additional prospective investigation of other regions of the canine body such as the knee, hip, carpal joint and the abdomen, offer a comparative and multidisciplinary atlas with useful applications in clinical veterinary medicine.

Dit werk beschrijft en illustreert dwarse anatomische doorsneden van verschillende klinisch belangrijke lichaamszones van de normale hond. Gelabelde anatomische snedes worden gebruikt om alle structuren op de corresponderende CT- en MR-beelden te identificeren. Deze gedetailleerde, vergelijkende beschrijving kan dienst doen als atlas voor de prakticus, daar het een optimale interpretatie van CT- en MR-beelden van honden met pathologische afwijkingen mogelijk maakt.

In het eerste hoofdstuk worden de CT- en MR-beelden bestudeerd van twee craniale gebieden, namelijk de hersenen en de neusgangen inclusief de paranasale sinussen.

Om CT- en MR-studies van de hersenen uit te voeren, werden 4 herdershonden verdoofd en in rugligging gepositioneerd. Tijdens het CT-onderzoek werden 2-mm dikke, pre-en postcontrast dwarse snedes gemaakt vanaf de lamina cribrosa van het zeeffbeen tot het craniale gedeelte van de atlas, hierbij gebruik makende van een weke delenvenster. Eén van de honden onderging vervolgens MR-onderzoek waarbij dezelfde positie als voor het CT-onderzoek werd behouden. Dwarse, 4-mm dikke T1-gewogen en T2-gewogen MR-beelden werden gemaakt van dezelfde zone van de schedel als bij het CT-onderzoek.

Eén van de honden onderging euthanasie, waarna de hersenen werden vrijgeprepareerd, gefixeerd, ingebed in gelatine en in 5-mm dikke, dwarse schijven gesneden met een mes. De anatomische doorsnedes werden gefotografeerd en een groot aantal hersenstructuren en verschillende delen van het ventrikelsysteem werden geïdentificeerd.

De meeste van deze structuren konden teruggevonden worden op de CT-beelden, gebruik makende van oriëntatiepunten zoals radiolucent cerebrosпинаalvocht en de omgevende beenderige weefsels. Helaas was het niet mogelijk om sommige onderdelen van het telencephalon te onderscheiden, meer bepaald de capsula interna en de gyrus hippocampi, noch sommige structuren van het diencephalon waaronder de tractus opticus, epiphysis, infundibulum en tuber cinereum. Van het mesencephalon waren de fossa intercruralis, nucleus ruber en substantia nigra niet identificeerbaar, en ter hoogte van het metencephalon konden de substantia alba van het cerebellum, de flocculus en de pedunculus cerebellaris medius niet worden gelokaliseerd. Sommige structuren van de medulla oblongata zoals de fissura mediana ventralis, de pyramis en het canalis centralis van de medulla spinalis waren onmogelijk te onderscheiden, evenmin als de plexus choroidei van de laterale en vierde ventrikels. Op de CT-beelden werden ook de beenderige en weke weefsels rondom de hersenen benoemd.

Bijna alle hersenstructuren die zichtbaar waren op de anatomische beelden konden worden geïdentificeerd op de MR-beelden, met uitzondering van sommige onderdelen van het diencephalon zoals de epiphysis, hypophysis met infundibulum en het corpus mamillare. Het onvermogen om deze structuren terug te vinden, was waarschijnlijk te wijten aan het feit dat deze laatste net niet in één van de snedes aanwezig waren. De nucleus ruber en substantia nigra van het mesencephalon konden eveneens niet gelokaliseerd worden, evenmin als de substantia alba van het cerebellum. Wanneer de MR-beelden vergeleken worden met de corresponderende CT-beelden kan worden besloten dat alle hersenstructuren en de omgevende zachte weefselstructuren veel beter zichtbaar zijn op de MR-beelden. Daarenboven konden verschillende structuren van de hersenen zoals de capsula interna, tractus opticus, gyrus hippocampi, colliculi rostrales et caudales, brachium pontis, fissura mediana ventralis, lobus floccularis, pyramis (ter hoogte van de medulla oblongata) en de plexus choroidei van de laterale en vierde ventrikels gemakkelijk worden gelokaliseerd op de MR-beelden, terwijl ze onherkenbaar waren op de CT-beelden. Alleen de beenderen van de schedel, met in het bijzonder de foramina, fossae, canales en sulci, waren veel duidelijker op de CT-beelden vergeleken met de MR-beelden.

Deze resultaten kunnen gebruikt worden als een basis voor evaluatie van CT- en MR-beelden van de hersenen van honden met pathologieën van het centraal zenuwstelsel.

Twee herdershonden werden gebruikt voor de CT- en MR-onderzoeken van de neusholte en paranasale sinussen. De eerste hond werd verdoofd en in rugligging geplaatst voor beide onderzoeken. Tijdens het CT-onderzoek werden 5-mm dikke dwarse snedes gemaakt vanaf het caudaal gedeelte van de frontale sinussen tot aan de neusgaten. Nadien werden deze CT-beelden afgedrukt op een botvenster. De hond onderging vervolgens een MR-onderzoek, waarbij T1-gewogen, T2-gewogen en proton-densiteit MR-beelden werden bekomen. Voor de tweede hond werd hetzelfde protocol gevolgd, met die uitzondering dat het dier in rugligging werd gepositioneerd met de kop loodrecht op de tafel teneinde dorsale beelden te bekomen. Op het einde van de onderzoeken ondergingen beide honden euthanasie en de schedels werden vrijgeprepareerd, ontkalkt, in gelatine ingebed en daarna met een mes in 5-mm dikke plakken gesneden. Elke anatomische doorsnede werd vergeleken met de corresponderende CT- en MR-beelden en alle herkenbare structuren werden gelabeld op alle beelden. De verschillende schedelbeenderen die de wand van de neusgangen vormen en de meeste onderdelen van de neusholte zoals de conchae nasales, de septa, meatussen en alle endo- en ectoturbinalia, konden

gemakkelijk geïdentificeerd worden op de anatomische figuren. De mediale en laterale delen van de frontale sinussen en de recessus maxillaris waren eveneens zichtbaar. Daarnaast werden ook verschillende omgevende structuren van het hoofd aangeduid.

Op de CT-beelden was het bovendien mogelijk om een groot aantal structuren van de neusgangen en paranasale sinussen te identificeren, met uitzondering van de dorsale, middelste en ventrale meatus en enkele van de ectoturbinalia. Ook een deel van de omgevende weke weefselstructuren kon niet onderscheiden worden.

Op de MR-beelden was het moeilijk om de verschillende schedelbeenderen te identificeren, doch de meeste konden worden gelokaliseerd aan de hand van hun 'leeg' signaal. In tegenstelling tot de beenderen waren de conchae, de conchale septa en de turbinalia –met uitzondering van enkele ectoturbinalia- gemakkelijk te onderscheiden dankzij het dunne laagje bedekkende mucosa. Ook de omgevende weke weefselstructuren waren zeer duidelijk zichtbaar op de MR-beelden, zeker wanneer vergeleken wordt met de CT-beelden.

Deze resultaten laten toe te besluiten dat de CT- en MR-beelden een nauwkeurige lokalisatie van alle structuren van de neusgangen en paranasale sinussen mogelijk maken. Bijgevolg kunnen beide technieken nuttig zijn voor het evalueren van neusaandoeningen.

In het tweede hoofdstuk van dit proefschrift werd de anatomie van de thorax beschreven zoals die gevisualiseerd wordt door CT en thoracoscopie. Vervolgens werd een vergelijkende studie tussen beide technieken gemaakt.

Voor CT-onderzoek van de thorax werden vier honden verdoofd en in rugligging gepositioneerd. Dwarse, 5 mm dikke CT-beelden werden gemaakt vanaf de borstingang tot aan het diafragma en werden bekeken gebruik makende van een weke delenvenster en een longvenster. Eén hond werd geëuthanaseerd en ingevroren, waarna de bevroren thorax in schijven van 10 mm dikte werd gezaagd. Bij elke anatomische snede werd een corresponderend CT-beeld gezocht en de anatomische structuren werden vergeleken.

Op de anatomische snedes waren de verschillende intrathoracale delen van het ademhalingsstelsel en de longlobben gemakkelijk zichtbaar. Ook de grote bloedvaten in de borstholte en in het craniale mediastinum konden eenvoudig worden geïdentificeerd. Andere intrathoracale structuren zoals het hart met zijn kamers en kleppen, de slokdarm, lymfeknopen en spieren waren eveneens eenvoudig te lokaliseren, evenals de verschillende delen van de thoraxwand en de omgevende weefsels. De meeste van de hierboven vermelde structuren van de thorax konden geïdentificeerd

worden op de CT-beelden met weke delenvenster, met uitzondering van de verschillende onderdelen van het hart, sommige bloedvaten, het ligamentum nuchae, het diafragma, de longlobben en de lobaire bronchen. Op de CT-beelden met longvenster waren alleen de verschillende delen van het ademhalingsstelsel zichtbaar en sommige grote bloedvaten. Van het hart en de lever konden alleen de contouren worden waargenomen, terwijl de positie van de slokdarm en van de cardia en fundus van de maag werd aangegeven door de aanwezigheid van lucht.

Voor thoracoscopie werden 4 honden verdoofd en in linker of rechter zijligging geplaatst. De endoscoop werd in de borstholte ingebracht via de bovenliggende zijde en ondertussen werden endoscopische foto's genomen. Een groot aantal intrathoracale structuren van de linker en rechter hemithorax waren endoscopisch zichtbaar.

Aan beide zijden waren de pulmonaire en costale pleura, het diafragma, het hart met pericardium en de onderdelen van de borstwand met de daarop verlopende zenuwen en bloedvaten gemakkelijk te onderscheiden. Zowel in de rechter als linker borstholte was het mogelijk om de slokdarm en trachea te lokaliseren in het craniale mediastinum.

In de linker borstholte werden de craniale en caudale longlobben bekeken en ook de grote bloedvaten zoals de aorta ascendens, aorta descendens en truncus pulmonalis. Aan de hartbasis waren het ligamentum arteriosum Botalli en de nervus laryngeus recurrens duidelijk zichtbaar, terwijl de linker nervus vagus en nervus phrenicus gelokaliseerd konden worden ter hoogte van het pericardium. In het craniale mediastinum werden de ductus thoracicus, de arteria subclavia sinistra en de vena brachiocephalica sinistra met hun takken geïdentificeerd.

In de rechter borstholte was het mogelijk om de craniale, middelste en caudale longlobben te evalueren en caudaal van het hart waren de vena cava caudalis en de rechter nervus phrenicus zichtbaar in de plica venae cavae. In het rechter craniale mediastinum konden daarenboven de vena azygos, vena cava cranialis, rechter nervus vagus en nervus phrenicus, vena broncho-esophagea en de ductus thoracicus worden bekeken.

Nadien werden deze beide technieken voor het onderzoek van de thorax met elkaar vergeleken. Tot de intrathoracale structuren die niet zichtbaar bleken op de CT-beelden maar eenvoudig te lokaliseren waren met thoracoscopie behoorden onder andere de pariëtale en viscerale pleura, het pericardium, de hartbasis met het ligamentum arteriosum Botalli, de ductus thoracicus, de plica venae cavae en verschillende intrathoracale zenuwen. Daarentegen was de identificatie van het

ruggenmerg, lymfeknopen, mediastinum en verschillende bloedvaten moeilijk tot onmogelijk via thoracoscopie maar eenvoudig via CT-onderzoek. Het uitwendig oppervlak van de verschillende longlobben (met uitzondering van de lobus accessorius) kon tijdens thoracoscopie bekeken worden, terwijl de inwendige details zichtbaar waren op de CT-beelden met longvenster. De onderdelen van het hart waren niet te onderscheiden tijdens het thoracoscopisch onderzoek mede door het ondoorzichtbare pericardium, maar ook op de CT-beelden was dit ten gevolge van bewegingsartefacten niet mogelijk.

Zowel thoracoscopie als CT van de thorax bieden een grote hoeveelheid aan intrathoracale anatomische informatie en kunnen gebruikt worden voor de diagnose van thoraxaandoeningen. De keuze tussen beide technieken zal vooral afhangen van de klinische voorgeschiedenis van het dier en van de resultaten van reeds gedane onderzoeken. Het feit dat thoracoscopie ook therapeutische mogelijkheden heeft, zal mede de definitieve keuze van de diagnostische techniek bepalen.

In het derde hoofdstuk van deze studie werd de CT- en MR-anatomie van twee regio's van de ledematen, namelijk de elleboog en de sprong, bestudeerd. Daarbij werden, voor elk gewricht, beide technieken met elkaar vergeleken.

Om het CT-onderzoek van de ellebogen uit te voeren, werden zes honden verdoofd en in zijligging geplaatst. Dwarse, 1 en 2 mm dikke CT-snedes werden bekomen vanaf de top van het olecranon tot 3 cm distaal van het ellebooggewricht en parallel met de humeroradiale gewrichtsspleet. De beelden werden bekeken gebruik makende van een botvenster en een weke delenvenster, en bijkomend werden sagittale en dorsale CT-reconstructies van het ellebooggewricht gemaakt. MR-onderzoek van de ellebogen werd uitgevoerd bij één van de honden (een Labrador retriever) waarbij het dier in dezelfde positie werd gehouden als tijdens het CT-onderzoek. Dwarse, 3 mm dikke, T1-gewogen en T2-gewogen beelden werden gemaakt van dezelfde regio als hierboven vermeld. Na de onderzoeken onderging de Labrador retriever euthanasie, waarna beide voorpoten werden verwijderd en ingevroren. Vervolgens werden de ellebogen in ongeveer 1 mm dikke schijfjes gesneden, gefotografeerd en vergeleken met de corresponderende CT- en MR-beelden.

Op de anatomische beelden waren verschillende beenderen, spieren, pezen, bloedvaten en zenuwen zichtbaar.

Dezelfde structuren waren te identificeren op de CT-beelden met weke delenvenster, met uitzondering van het ligamentum anulare van de radius en de membrana interossea antebrachii.

Alle beenderige structuren die gelokaliseerd waren op de anatomische beelden konden ook worden aangeduid op de CT-beelden met beenvenster, en het volledige humero-radiaal gewrichtsoppervlak kon geëvalueerd worden op de CT-reconstructies.

Alle structuren zichtbaar op de anatomische beelden waren ook aanwezig op de MR-beelden; alleen de arteria mediana, nervus medianus en nervus radialis konden niet gelokaliseerd worden.

Vervolgens werden de MR-beelden vergeleken met de corresponderende CT-beelden met weke delenvenster. Met uitzondering van de hogervermelde leidingen, die niet zichtbaar waren op de MR-beelden, werden dezelfde structuren onderscheiden. Anderzijds was het ligamentum anulare van de radius zeer duidelijk op de MR-beelden en onmogelijk te identificeren op de CT-beelden.

De meeste anatomische structuren van het ellebooggewricht zijn herkenbaar op CT- en MR-beelden. Bijgevolg kunnen deze resultaten gebruikt worden als een naslagwerk voor de beoordeling van CT- en MR-beelden van de ellebogen van honden met letsels en ontwikkelingsstoornissen of degeneratieve aandoeningen van dit gewricht.

Om het CT-onderzoek van de sprongen uit te voeren, werden zes honden verdoofd en in rugligging gepositioneerd. Dwarse, 1 en 2 mm dikke CT-snedes werden bekomen vanaf het meest proximale punt van de calcaneus tot 1 cm distaal van het tarsometatarsaal gewricht, gebruik makende van een botvenster en een weke delenvenster. Nadien werden CT-reconstructies gemaakt van het tarsocruraal gewricht in sagittale en dorsale vlakken. Het MR-onderzoek van de tarsi werd uitgevoerd bij één van de honden waarbij het dier in dezelfde positie werd gehouden als op de CT-tafel. Dwarse T1-gewogen en T2-gewogen beelden werden gemaakt met een dikte van 3 mm. Na euthanasie van één van de honden werden de achterpoten verwijderd en ingevroren, waarna de spronggewrichten in 1 mm dikke schijfjes werden gesneden. Vervolgens werden de anatomische doorsnedes gefotografeerd en vergeleken met de corresponderende CT- en MR-beelden.

Alle beenderen, pezen en bloedvaten zichtbaar op de anatomische snedes werden gelabeld. Deze structuren werden eveneens teruggevonden op de CT-beelden met weke delenvenster, met uitzondering van de musculus extensor digitorum brevis en het ligamentum talocalcaneum interosseum. Op de CT-beelden met botvenster konden alleen de beenderen worden benoemd, terwijl het volledige tarsocrurale gewrichtsvlak kon worden geëvalueerd op de sagittale en dorsale CT-reconstructies.

Alle beenderige en zachte weefselstructuren die zichtbaar waren op de anatomische beelden, werden ook onderscheiden op de MR-beelden. Wanneer deze laatste werden vergeleken met de

corresponderende CT-beelden, konden niet alleen dezelfde structuren gelokaliseerd worden op de MR-beelden, maar tevens ook de musculus extensor digitorum brevis en het ligamentum talocalcaneum interosseum. In het algemeen waren bloedvaten en pezen duidelijker te zien op de MR-beelden in vergelijking met de CT-beelden.

Deze gedetailleerde atlas van het tarsaalgewricht leent zich als een uitstekende anatomische basis voor de evaluatie van CT- en MR-beelden van honden met letsels van de sprong.

De bevindingen van deze studie, samen met de resultaten van bijkomende toekomstige onderzoeken van andere lichaamszones van de hond, zoals de knie, de heup, de carpus en het abdomen, bieden een vergelijkende en multidisciplinaire atlas die van groot nut kan zijn in de klinische diergeneeskunde.

Een doctoraat maken leek mij altijd een onbereikbare droom, temeer daar ik na 2 jaar voltijds assistente aan de vakgroep Morfologie gekozen had voor een eigen praktijk. Wel bleef ik als deeltijds assistente practica anatomie en histologie geven. Prof. P. Simoens bood mij de kans om daarnaast verder wetenschappelijk onderzoek te verrichten en publicaties te maken, wat ik ook met groot enthousiasme aanvaardde. Met zijn goede raad en opbouwende kritiek leidde hij mijn schrijfsels in goede banen. Zijn nimmer afnemend enthousiasme was voor mij een enorme stimulans. Ook toen ik naar de vakgroep Medische Beeldvorming overstapte, kon ik voor mijn publicaties verder op zijn steun en advies rekenen. Voor dit alles en het feit dat hij als mede-promotor voor dit doctoraat wou optreden, ben ik hem zeer dankbaar.

Gedurende mijn periode als assistente Morfologie was er ook een hechte samenwerking met Prof. H. van Bree. Mijn opgedane anatomische kennis was een enorme hulp voor onze onderzoeksprojecten, die – dankzij mijn ‘schrijversopleiding’ - resulteerden in enkele publicaties omtrent echografie. Later, als assistente op de vakgroep Medische Beeldvorming had ik de mogelijkheid om mij te verdiepen in de interpretatie van CT-beelden. Ondertussen opperde Prof. Van Bree het idee om hieromtrent een doctoraat te maken. Dankzij zijn overtuigingskracht en zijn geloof in mijn ‘kunnen’ is mijn droom dan ook werkelijkheid geworden. De lovende woorden van mijn diensthoofd en tevens promotor smoorden steeds al mijn twijfels. Met zijn goede ideeën en scherpe kijk op zaken legde hij de basis van dit werk. Ik dank hem voor het vertrouwen dat hij in mij had en voor de vrijheid die hij me gaf, zodat ik zelfstandig en op eigen tempo dit werk kon vervolmaken.

Elke woensdag dit doctoraat verder opbouwen was dan ook geen opgave voor mij maar iets waar ik elke week naar uitkeek. Een bijkomende stimulans was de aanwezigheid van mijn toffe collega’s, in het bijzonder van Dr. Ingrid Gielen. Door samen in eenzelfde bureau te werken, elkaar te helpen en moed in te spreken, en daarnaast nog eens samen te paard onze gepijnigde hersenen te laten uitwaaien aan zee, werd zij meer een vriendin dan medewerkster. Ik bewonder haar belangloze inzet voor de dienst en haar internationale uitstraling. Dankzij haar bijdrage, voornamelijk bestaande uit talrijke CT- en MR-beelden, is dit werk tot stand gekomen. Ik ben haar zeer dankbaar en hoop dat onze samenwerking ook in de toekomst productief, en vooral ontspannen en plezierig mag blijven.

Mijn dank gaat ook uit naar Prof. em. F. Verschooten. Ik heb hem leren kennen als een man met enerzijds sterke principes en anderzijds vaderlijke bezorgdheid. Zijn wijsheid, en niet alleen op wetenschappelijk vlak, vervulde mij met groot respect. Ik was dan ook verheugd dat hij mij als assistente wou aannemen en hoop dat hij dit doctoraat als een teken van dank wil beschouwen.

Ook dank aan Dr. Jimmy Saunders voor de leuke samenwerking die ‘wortel schoot’ ten tijde van zijn doctoraat. De wederzijdse hulp afgewisseld met een prettige babbel was de aanzet tot een verdere vriendschap. Ik kijk op naar zijn wetenschappelijke kennis, de inzet voor zijn werk en zijn volharding om een doel te bereiken. Ik dank hem ten eerste voor zijn inbreng in dit doctoraat en zijn begeleidende hulp.

Mijn andere collega's van de vakgroep, met name Dr. Annemie Van Caelenberg, Dr. Barbara Vandevelde, Prof. Bernadette van Ryssen, Dr. Frank Coopman, Marleen Goethals en Claudine Van Sante wil ik bedanken voor het creëren van de toffe werksfeer en voor de welgemeende interesse in mijn persoon en werk.

Met Marnix Verdonck heb ik ettelijke uren aan de computer doorgebracht. Hij stond steeds klaar om me te helpen met het bewerken van de beelden van dit doctoraat. Ook leerde hij mij omgaan met verschillende computerprogramma's zoals Thumbs en Paint, zodat ik wat onafhankelijker van hem werd. Als multivalente techniker nam hij ook alle foto's van de anatomische snedes en ontwierp zelfs een speciale zaag om de hersenen te snijden. Daartussen vond hij ook altijd tijd voor een grapje. Kortom, zonder hem was ik verloren. Erg bedankt voor je hulp en immer opgewekt humeur, Marnix!

Patrick Vervaeke van de Vakgroep Morfologie wil ik niet alleen danken voor het versnijden van de anatomische stukken maar ook voor zijn vriendschap die sinds onze samenwerking in de snijzaal morfologie niet meer stuk kan.

Dr. Ingeborg Polis dank ik voor de samenwerking tijdens de thoracoscopieën. Studenten Olaf Thas en Sofie Van de Meervenne voor hun thesissen die het voorbereidend werk voor mijn publicaties vereenvoudigden.

Verder ben ik de andere leden van de begeleidings- en examencommissie Dr. J Vandevenne en Prof. Dr. H. Waibl zeer erkentelijk. Hun kritische commentaren en hun nauwkeurig verbeterwerk leverden een grote bijdrage bij het tot stand komen van dit werk. Dr. Vandevenne wil ik daarnaast danken voor het uitvoeren van de MR onderzoeken.

En dan mijn lieve ouders die mij al hun hele leven koesteren en stimuleren, en mij een onbezorgde jeugd en alle kansen om te studeren gaven. De wens -die ik als kind reeds had- om dierenarts te worden, hebben zij helpen vervullen. Mentaal en fysiek hebben ze me steeds gesteund. Nachtenlang bleef mijn moeder wakker bij haar studerende dochter, omdat ze wist dat haar aanwezigheid mij de moed gaf voor het volgende examen. Mijn vader gaf me daarnaast ook de financiële steun die nodig was om als pas afgestudeerde een eigen praktijk te starten. Met hard werken probeer ik hen een stuk van mijn enorme dankbaarheid te tonen. Dit doctoraat beschouw ik dan ook als een eerbetoon aan hen die dit allemaal mogelijk maakten.

En natuurlijk wil ik ook Johan danken. Mijn man en tevens beste vriend die mij een stabiele relatie gaf en de ruimte om mijn dromen op werkvlak te realiseren. Ik kreeg daarenboven zijn onvoorwaardelijke liefde én twee schatten van kindjes : Manon en Héloïse. Ook de steun en interesse van mijn schoonouders, zus, schoonzus, schoonbroers en onze vele vrienden en vriendinnen waren een hart onder de riem. Zij allen maken het leven zo veel aangenamer. Het geluk in mijn privéleven gaf me de energie om aan dit doctoraat te werken en weerspiegelt zich elke dag in mijn beroep als dierenarts, een beroep dat ik met steeds toenemend plezier, overtuiging en voldoening uitoefen.

Lieve

Lieve De Rycke werd geboren op 17 april 1966 te Brugge. Na het behalen van het diploma hoger secundair onderwijs aan het Onze-Lieve-Vrouw-Hemelvaart-Instituut te Brugge begon zij in 1984 met de studie Diergeneeskunde aan de Universiteit Gent. Gedurende haar laatste studiejaar begeleidde ze de practica anatomie als leerling-assistente bij de vakgroep Morfologie van de Huisdieren. Aan dezelfde vakgroep voltooide zij haar eindstudiewerk "European Brown Hare Syndrome in België" waarmee ze de Norden-Wetenschappelijke prijs won. In 1990 behaalde ze het diploma van Doctor in de Diergeneeskunde met grote onderscheiding.

Onmiddellijk daarna trad zij als assistente in dienst bij de Vakgroep Morfologie van de Huisdieren waar zij het onderricht van de practica anatomie en histologie verzorgde. Daarnaast startte ze een eigen praktijk Kleine Huisdieren te Brugge. Daar haar interesse eveneens uitging naar de medische beeldvorming was zij vanaf 1995 ook actief als navorser bij de Vakgroep Medische Beeldvorming van de Huisdieren. In 1999 stopte ze haar activiteiten bij de vakgroep Morfologie en werd zij bij de vakgroep Medische Beeldvorming aangenomen als 20% assistente. Gedurende de laatste jaren heeft zij zich verdiept in het anatomisch interpreteren van CT-beelden van de hond, wat heeft geleid tot dit proefschrift.

Lieve De Rycke is auteur of mede-auteur van 13 publicaties in internationale en nationale tijdschriften en nam actief deel aan verschillende nationale en internationale congressen.
